Abstract

The rate of land ice loss due to iceberg calving is a key source of variability among model projections of 21st century sealevel rise. It is especially challenging to account for mass loss due to iceberg calving in Greenland, where ice drains to the ocean through hundreds of outlet glaciers, many smaller than typical model grid scale. Here, we apply a numerically efficient network flowline model (SERMeQ) forced by surface mass balance to simulate an upper bound on decadal calving retreat of 155 grounded outlet glaciers of the Greenland Ice Sheet—resolving five times as many outlets as was previously possible. We show that the upper bound holds for 91% of glaciers examined and that simulated changes in terminus position correlate with observed changes. SERMeQ can provide a physically consistent constraint on forward projections of the dynamic mass loss from the Greenland Ice Sheet associated with different climate projections.

SERMeQ model produces a realistic upper bound on calving retreat for 155 Greenland outlet glaciers

14 Abstract

The rate of land ice loss due to iceberg calving is a key source of variability among model 15 projections of 21st century sea-level rise. It is especially challenging to account for mass 16 loss due to iceberg calving in Greenland, where ice drains to the ocean through hundreds 17 of outlet glaciers, many smaller than typical model grid scale. Here, we apply a numer-18 ically efficient network flowline model (SERMeQ) forced by surface mass balance to sim-19 ulate an upper bound on decadal calving retreat of 155 grounded outlet glaciers of the 20 Greenland Ice Sheet—resolving five times as many outlets as was previously possible. 21 We show that the upper bound holds for 91% of glaciers examined and that simulated 22 changes in terminus position correlate with observed changes. SERMeQ can provide a 23 physically consistent constraint on forward projections of the dynamic mass loss from 24 the Greenland Ice Sheet associated with different climate projections. 25

²⁶ 1 Introduction

The Greenland Ice Sheet is currently the largest single contributor to global mean 27 sea level rise (van den Broeke et al., 2017). It discharges ice mass to the ocean through 28 three main processes: release of surface meltwater, submarine melting where ice is in con-29 tact with the ocean, and the detachment (calving) of icebergs. The ice mass lost to sub-30 marine melting has only recently been directly observed (Sutherland et al., 2019) and 31 remains difficult to estimate for the whole ice sheet (Beckmann et al., 2018), but it is 32 33 clear that enhanced surface melting and calving processes have resulted in increased mass discharge since the late 1990s (van den Broeke et al., 2016; Enderlin et al., 2014; Khan 34 et al., 2014). 35

Processes that control surface melt are increasingly resolved in regional models (Mottram 36 et al., 2017; Noël et al., 2018). Iceberg calving, by contrast, remains poorly understood, 37 with multiple contradictory parameterizations incorporated into ice sheet/glacier mod-38 els (Benn, Cowton, et al., 2017; Morlighem et al., 2016; Levermann et al., 2012). Fur-39 thermore, iceberg calving can remove mass more rapidly than is possible through melt-40 ing alone, contributing to rapid tidewater glacier retreat through mechanisms like tide-41 water glacier instability (Meier & Post, 1987) and the recently-described Marine Ice Cliff 42 Instability (Bassis & Walker, 2012; Pollard et al., 2015). 43

Simulating discharge from the Greenland Ice Sheet is further complicated by the 44 local factors affecting ice discharge at the nearly 200 outlet glaciers that connect the ice 45 sheet to the ocean (e.g. Catania et al., 2018; Enderlin et al., 2018). For all but the largest 46 outlets, iceberg calving occurs at smaller scales than are captured in continental-scale 47 ice sheet models. Existing estimates of dynamic mass loss from Greenland outlets have 48 come from extrapolating perturbations on the largest outlets (Price et al., 2011; Nick 49 et al., 2013), simulating the sea level contribution from only selected outlets (Choi et al., 50 2017; Morlighem et al., 2019), or simulating the entire ice sheet at a spatial resolution 51 of 500 m (Aschwanden et al., 2016, 2019) to resolve about 30 of the nearly 200 glaciers 52 that drain the Greenland Ice Sheet. 53

Despite these achievements, more than 100 outlet glaciers, responsible for $\sim 1/3$ 54 of current Greenland Ice Sheet discharge (Enderlin et al., 2014), are not routinely sim-55 ulated, and their dynamics cannot necessarily be inferred from the dynamics of larger 56 outlets. Another layer of spatial complexity arises in that many outlet glaciers collect 57 ice from several interacting tributary branches that are themselves also smaller than typ-58 ical ice sheet model grid scale. The small scale of tributary glacier networks feeding out-59 lets makes them especially challenging to simulate in continental ice sheet models, re-60 quiring model resolution of hundreds to tens of meters to adequately resolve. 61

⁶² A more fundamental challenge in projecting mass loss due to calving is the incom-⁶³ patibility of fracture-driven iceberg calving with the assumption of continuum deforma-

tion inherent in most ice sheet models (e.g. Price et al., 2015; Winkelmann et al., 2011; 64 Greve, 2000). Simple empirical parameterizations can relate calving rate to continuous 65 variables, such as proglacial water depth (Brown et al., 1982; Hanson & Hooke, 2000), 66 but may not hold into the future as climate forcing enters a new statistical regime. Physically-67 based calving laws, such as the fracture field approach developed by Albrecht and Lev-68 ermann (2012) or von Mises calving law developed for Greenland by Morlighem et al. 69 (2016), often impose an empirically-adjustable calving rate parameter. Recent work has 70 sought to simulate ice failure using continuum damage mechanics, with some success in 71 a variety of case studies (Borstad et al., 2012; Duddu et al., 2013; Krug et al., 2014; Sun 72 et al., 2017; Mercenier et al., 2019). However, at present the evolution of the damage field 73 through a damage production function is also empirical, with multiple tuned parame-74 ters that are poorly constrained by laboratory or field measurements (Emetc et al., 2018). 75 Another recent approach couples a granular model that allows true fracture and calv-76 ing to a finite-element model that solves an approximation to the Stokes equations for 77 viscous deformation, offering a very promising basis for process-scale simulation of fully-78 dynamic calving (Benn, Aström, et al., 2017). Unfortunately, the coupled approach re-79 mains too computationally expensive for century-scale projections. Despite their promise, 80 neither continuum damage models nor granular calving models have been able to repro-81 duce observed multi-annual evolution of calving front positions in Greenland. 82

Improving projections of 21st-century sea level rise requires models that can (i) re-83 produce complex patterns of glacier advance and retreat currently observed in Green-84 land and *(ii)* efficiently simulate dynamic discharge and iceberg calving from individ-85 ual outlet glaciers for a spectrum of climate scenarios. To address this, we have devel-86 oped a simple model to simulate advance, retreat, and dynamic mass loss due to calv-87 ing on networks of marine-terminating glaciers (Ultee & Bassis, 2016, 2017; Bassis & Ul-88 tee, 2019). Our model framework, called SERMeQ, is able to directly simulate decade-89 to-century-scale evolution of hundreds of outlet glaciers in response to surface mass bal-90 ance forcing across multiple climate scenarios. This explicit simulation capability, together 91 with recent observations of more than 200 Greenland outlet glacier termini (Joughin et 92 al., 2015, updated 2017a), makes it possible to evaluate our model's performance in a 93 wide range of glacier environments. Here, we show that SERMeQ bounds retreat rates, 94 and reproduces patterns of present-day observed changes in terminus position of 155 Green-95 land outlet glaciers, providing one of the largest validations of any calving parameter-96 ization. On the basis of this validation, our model physics can be incorporated into global 97 glacier and ice sheet models to compute a physically-consistent upper constraint on the 98 century-scale glaciological contribution to global sea level rise. 99

100 2 Methods

101

2.1 SERMeQ ice dynamics model

SERMeQ—the Simple Estimator of Retreat Magnitude and ice flux (Q), sermed 102 meaning "glacier" in Greenlandic—is a width-averaged, vertically-integrated model that 103 determines centerline glacier surface elevation corresponding to a given terminus posi-104 tion. The ice dynamics are based on a perfectly-plastic limiting case of a viscoplastic rhe-105 ology (Nye, 1951; Bassis & Ultee, 2019), with modifications to allow calving at a grounded 106 ice-water interface (Ultee & Bassis, 2016) and interaction between multiple tributary glaciers 107 (Ultee & Bassis, 2017). Our flowline-modeling approach is compatible with other flowline-108 based models such as the Open Global Glacier Model (Maussion et al., 2019), but SER-109 MeQ focuses specifically on near-terminus dynamics of marine glaciers to simulate the 110 calving process. 111

Rather than imposing an empirical calving rate, SERMeQ self-consistently calculates the maximum rate of terminus advance or retreat at each time step for a given climate forcing. Terminus position evolves in response to near-terminus stretching, bedrock topography, and changes in catchment-wide surface mass balance as described in Ultee (2018) and Bassis and Ultee (2019),

$$\frac{dL}{dt} = \frac{\dot{a} - H\frac{\partial U}{\partial x} - U\frac{\partial H}{\partial x}}{\frac{\partial H_y}{\partial x} - \frac{\partial H}{\partial x}}.$$
(1)

In Equation 1, H = H(x,t) is the ice thickness, U = U(x,t) the ice velocity, $\dot{a} = \dot{a}(x,t)$ 117 the net ice accumulation rate, H_y the thickness at which effective stress within the ice 118 reaches its yield strength (Equation S1), and all terms are evaluated at the instantaneous 119 terminus position, x = L(t) (see Supplementary Text S1-2). For a change in terminus 120 position determined from Equation 1, SERMeQ calculates a new steady-state glacier sur-121 face elevation profile and calculates change in glacier volume above buoyancy (Supple-122 mentary Figure S1). The latter produces a net contribution to global mean sea level (ex-123 ample in Supplementary Text S1, not evaluated in this validation exercise). 124

The only adjustable model parameters are ice temperature T, which is used to calculate the horizontal stretching rate $\partial U/\partial x$ at the terminus, and yield strength τ_y , which is used to calculate the yield thickness H_y (Supplementary Text S1-S3). Both are material quantities that can be independently constrained by laboratory and field measurements. Crucially, we do not tune either of our parameters to match changes in terminus position. Comparison of simulated with observed terminus position thus provides a completely independent validation.

Here, we extend the physical realism and applicability of our model to demonstrate that it can simulate calving retreat of a wide variety of marine-terminating glaciers. Novel elements of SERMeQ specific to this application include upstream forcing with surface mass balance from a regional climate model (Mottram et al., 2018) and the automatic selection of networks of flowlines with varying width (traced from Joughin et al., 2015, updated 2017b, see Supplementary Text S5).

138

2.2 Identification of flowline networks

We first identified 181 Greenland outlet glaciers that have multiple terminus po-139 sitions recorded in Joughin et al. (2015, updated 2017a). For each glacier, we then de-140 fined a network of interacting flowlines with spatially variable width by tracing ice sur-141 face velocity from Joughin et al. (2015, updated 2017b, and see Supplementary Text S5). 142 We extracted ice surface and bed elevation from BedMachine version 3 (Morlighem et 143 al., 2017) and applied a Gaussian filter to produce width-averaged topography. Where 144 the data suggested the presence of short, transient ice tongues, we removed the floating 145 portion from consideration and simulated the grounding line as the "terminus". We re-146 moved three glaciers with long, persistent ice tongues, as SERMeQ is unable to simu-147 late ice tongue evolution. Thirteen of the 181 outlets had initial termini grounded above 148 sea level and iceberg calving is thus unlikely to dominate dynamic mass changes there. 149 We removed those thirteen glaciers from consideration as well. Noisy or missing data that 150 produced unphysical bed topography caused us to remove ten additional outlets, leav-151 ing 155 glaciers for our analysis. 152

For the remaining 155 outlet glaciers, we defined the initial terminus as the grounded-153 ice point along our central flowline that lies closest to the centroid of the 2006 terminus 154 reported in Joughin et al. (2015, updated 2017a). We optimized a single parameter, the 155 yield strength of ice, to best fit the 2006 observed surface profile, as described in Ultee 156 and Bassis (2017). We used a best-guess ice temperature T of -10° C for all glaciers. 157 We then found the catchment-wide, annual mean surface mass balance forcing for each 158 outlet, \dot{a} in Equation 1, from HIRHAM regional climate model reanalysis (Mottram et 159 al., 2018; Rae et al., 2012; Lucas-Picher et al., 2012), and simulated resulting changes 160 between 2006 and 2014 in ice extent (Figures 1-3) and volume above buoyancy (Figure 161 4 and Supplementary Figure 1). Finally, we compared the simulated changes in termi-162

¹⁶³ nus position with observed changes reported in Joughin et al. (2015, updated 2017a) for ¹⁶⁴ the same period. Because our optimization of τ_y considers only the initial observed sur-¹⁶⁵ face profile, and the changes in terminus position are an independent response to changes ¹⁶⁶ in surface mass balance, this comparison examines an independent model prediction that ¹⁶⁷ is not tuned to match observations.

2.3 Comparison with observations

We extracted all available terminus position records from (Joughin et al., 2015, up-169 dated 2017a) for each year within our simulated period: 2006, 2007, 2009, 2013, and 2014. 170 Each terminus position record consists of one or more points; records with multiple points 171 trace across-flow variation in terminus position. We projected all available points from 172 a given record onto the central flowline of the corresponding glacier network, and we iden-173 tified the space between the most seaward and most landward points of that projection 174 as the "observational range". We also tracked the change over time in the position of 175 the terminus centroid projected on the flowline, which we identified as the "observed (terminus-176 centroid) retreat rate". Finally, we compared the simulated retreat rates with the ob-177 served terminus-centroid retreat rates (Figure 2) and the simulated terminus positions 178 with the observational range (Figures 3-4a). 179

180 **3 Results**

193

168

3.1 An upper bound on calving retreat for 155 Greenland outlets

Figure 1 shows the total retreat we simulated for each glacier between 2006 and 194 2014, arranged by approximate outlet position. SERMeQ simulates less than 5 km of 195 length change during the observed period on most outlets. There is no relationship be-196 tween outlet glacier latitude and magnitude of upper-bound retreat: simulated glacier 197 response to downscaled climate reanalysis forcing is not a simple function of annual av-198 erage temperature. Dynamic glacier response depends on glacier geometry, as previous 199 studies have also highlighted (Felikson et al., 2017; Benn, Cowton, et al., 2017; Catania 200 et al., 2018). 201

Equation 1 includes an assumption that the glacier calving front is a yield surface, 202 which produces a theoretical upper bound on calving retreat for a given glacier geom-203 etry and surface mass balance (see Bassis & Ultee, 2019). Thus, provided there are no 204 significant errors in the bed geometry and surface mass balance used, we anticipate that 205 SERMeQ-simulated rates of retreat will generally overestimate observed rates. Figure 206 2 shows that SERMeQ satisfies this expectation and overestimates retreat for 91% (108/119) 207 of glaciers for which more than two terminus position observations are available to con-208 strain the observed retreat rate. 209

The bulk model results shown in Figures 1 and 2 summarize multi-annual change 215 in terminus position simulated across Greenland. Figure 3 compares observed and sim-216 ulated terminus position change for example glaciers where SERMeQ underestimates, 217 overestimates, or correctly captures the observed rate of retreat. Apuseeq Anittangasikkaa-218 juk, which is 2 km wide at the terminus and has a small floating ice tongue, is one of a 219 handful of outlets where SERMeQ underestimates observed retreat (Fig. 3a). The sim-220 ulated terminus positions are still within the (small) observational range in that case. 221 SERMeQ strongly overestimates retreat of Helheim Glacier, a large and high-flux glacier 222 on Greenland's east coast whose terminus approaches flotation (Fig. 3b). On Sermeq Ku-223 jalleq (Danish: Jakobshavn Isbræ), a very large and well-studied outlet glacier on the 224 southwest coast of Greenland, the simulated retreat of 6 km is comparable to observed 225 retreat (Fig. 3c). 226

Map view of the 2006-2014 retreat simulated in this work. Bars indicate magnitude Figure 1. 181 of simulated retreat for each glacier, with glaciers identified and ordered by their MEaSURES 182 outlet glacier ID number (1-200). Glacier ID 1, which is in the Disko Bay region, appears in the 183 lower left; glacier IDs increase clockwise around the map border. Blue diamonds mark the map 184 location of each outlet we simulated, and every 10th glacier ID is labelled and connected to its 185 outlet location in black. A table of MEaSUREs glacier IDs and names appears in the Supple-186 mentary Material. Border spaces with no bar correspond to outlets where data was not sufficient 187 to initialize a SERMeQ simulation, or where our analysis indicated SERMeQ would not be ap-188 plicable (see Section 2). Yellow bars and map stars show the case-study glaciers highlighted in 189 Figure 3. Coloured overlay on the satellite map is ice velocity derived from Sentinel-1 observa-190 tions (ENVEO, 2017), shown on a logarithmic scale such that fast-moving outlet networks appear 191 brighter than slow-moving inland ice. 192

Figure 2. Comparison of observed and simulated rate of retreat for all glaciers simulated. Markers indicate the slope of linear fits to the observed (x-axis) and simulated (y-axis) terminus positions over the 2006-2014 period. Error bars indicate the error on each linear regression. Open circles indicate oscillating termini that are not well captured by linear regression to simulated position (p>0.05; n = 9).

Figure 3. Comparisons of observed and simulated terminus position change for (a) Apuseeq 227 Anittangasikkaajuk (glacier ID 137), where SERMeQ underestimates the true rate of retreat; (b) 228 Helheim Glacier (glacier ID 175), where SERMeQ overestimates retreat; (c) Sermeq Kujalleq 229 (glacier ID 3), where SERMeQ captures observed retreat. Black curves indicate SERMeQ-230 simulated terminus positions, while blue markers indicate MEaSUREs observations. The blue 231 lines show the most-advanced and most-retreated parts of the terminus projected onto the cen-232 terline, and blue diamonds indicate the centroid of the observed terminus projected onto the 233 centerline. Lower left corner annotations give Spearman's rank correlation coefficient ρ between 234 observed and simulated terminus position change for each glacier. Plots share both x- and y-axis 235 scales. 236

Figure 4. Histograms of (a) Range-normalized difference in terminus position, where the simulated terminus position $x_{\text{term.sim.}}$ is compared with the centroid of the observed terminus c_{obs} and normalized by the range of observed terminus positions (max_{obs} - min_{obs}) along the flowline in the same year; and (b) Spearman's rank-correlation coefficient, ρ , between observed and simulated terminus positions for all glaciers.

3.2 Upper bound retreat rates are realistic

A useful upper bound on calving retreat would consistently overestimate the rate of retreat (Figure 2), simulate terminus positions relatively close to observed termini, and correlate with observed changes. We quantify SERMeQ's performance on the latter indicators in Figure 4.

The histogram in Figure 4a summarizes 404 comparisons of simulated versus ob-247 served terminus positions, normalized by each glacier's observational range for each year, 248 such that values within ± 1 indicate simulated terminus positions within the observed 249 range. 40% of simulated terminus positions fall within that range, and 55% of simulated 250 terminus positions are within twice the range of the observed—that is, the simulations 251 are relatively close to the observations. Most simulated terminus positions are more re-252 treated than the observed (positive x-axis values in Figure 4), as expected for an upper 253 bound. 254

Because we present an upper bound on retreat rather than a calibrated model fit, 255 we do not expect a linear relationship between simulated and observed retreat. Instead, 256 we assess Spearman's rank correlation coefficient for each glacier's terminus positions over 257 time. The coefficient ρ ranges from -1 to 1, where positive ρ indicates that retreat is 258 observed when the model simulates retreat, advance is observed when the model sim-259 ulates advance, and larger magnitudes of observed and simulated change correspond. Of 260 the 155 glaciers we simulate, ρ is positive for 103, as shown in Figure 4b. For 62 glaciers 261 simulated, $\rho \geq 0.5$ and significant at the p < 0.1 level, which indicates a moderately 262 strong and statistically significant relationship between simulated and observed termi-263 nus position over time. Only 2 glaciers have negative ρ significant at the same level. The 264 mean ρ over all 155 glaciers is 0.5. 265

²⁶⁶ 4 Discussion

Our simulated upper-bound rate of terminus retreat/advance emerges as a dynamic 267 glacier response to climate forcing and glacier geometry (Equation 1) and does not rely on any tuning to match observations. The two model parameters, yield strength of glacier 269 ice τ_y and ice temperature T, are physical quantities constrained by laboratory and field 270 observations, and neither is optimized against observed retreat rates. The yield strengths 271 we use for most Greenland outlet glaciers simulated here range from 50-250 kPa (Sup-272 plementary Text S3), well within the range of 50-500 kPa suggested by previous works 273 (Nimmo, 2004; O'Neel et al., 2005; Cuffey & Paterson, 2010). We use an ice tempera-274 ture of -10° C, which is also within the range expected from simple physical scaling (van der 275 Veen, 2013), observations (Clow et al., 1996), and modeling (Greuell & Konzelmann, 1994). 276 It is possible an improved match to observed retreat rates could be found if we did al-277 low parameters to vary within and between glacier catchments or over time. However, 278 that would sacrifice the physical upper bound in favor of empirical tuning that cannot 279 be independently constrained by laboratory or field observations. 280

The upper-bound retreat rate computed from Equation 1 can far exceed the ob-281 served rate, as shown in Figures 2 and 3b. There are three notable sources of discrep-282 ancy between the modelled and observed retreat rates shown in Figures 2-4: (1) qual-283 ity of available model input data, (2) performance of automated flowline selection algo-284 rithm, and (3) presence of floating ice. First, on small outlets that are rarely visited or 285 studied in detail, the bed topography and climate reanalysis data used as input for SER-286 MeQ may be poorly constrained. As a result, the simulated glacier evolves in response 287 to conditions that do not accurately reflect the local environment, and the simulated change 288 in terminus position is more likely to be inaccurate. Second, on small or slow-moving out-289 lets, or where there are gaps in Sentinel-1 velocity data, our method for tracing flowlines 290 (Text S5) is prone to error. As a result, the simulated glacier has unrealistic geometry 291

and may flow over bedrock features that are not present in a true central flowline of the 292 outlet. Finally, where floating tongues are present, we remove them and simulate the first 293 grounded grid point as the "terminus". This can change the near-terminus stress state, 294 in some cases exposing an unstable wall of thick ice and initiating rapid retreat. Effects (1) and (2) are likely responsible for the underestimated retreat of Apuseeq Anittangasikkaa-296 juk; effect (3) is likely responsible for the overestimated retreat of Helheim Glacier (see 297 Supplementary Text S6). The first two effects can be mitigated with improved obser-298 vational data and manual data processing where possible. The third effect reflects upper-299 bound retreat dynamics that are currently held in check by floating ice, but which we 300 speculate could be activated if that floating ice were removed. 301

The 91% satisfaction of the intended upper bound on retreat rate (Figure 2) sup-302 ports the utility of our model for producing upper bounds on calving retreat and dynamic 303 mass loss. In contrast to existing estimates of 21st-century calving loss, our approach 304 does not impose a uniform calving rate or outlet glacier speedup factor (Pfeffer et al., 305 2008; Graversen et al., 2011; Goelzer et al., 2013; DeConto & Pollard, 2016; Goelzer et 306 al., 2020, accepted); instead, we calculate a theoretical maximum rate of calving retreat 307 that can vary by glacier (Bassis & Ultee, 2019). The result is a physically consistent bound 308 on terminus position change that correlates with observed changes for most glaciers (Fig-309 ure 4b). By contrast, simpler bounding methods such as imposing a fixed minimum ter-310 minus position would have no relationship ($\rho = 0$) with observed terminus position change. 311 Further, our model can track terminus retreat and mass loss from multiple interacting 312 branches of a glacier tributary network (Ultee & Bassis, 2017; Ultee, 2018), ensuring that 313 potentially important contributions to sea level are not overlooked. Within ice-sheet-scale 314 models, our method could be implemented as a calving criterion at grounded ice-ocean 315 interface cells or used as a module to enhance resolution of outlet glacier networks. 316

The current version of SERMeQ does not explicitly simulate frontal ablation by 317 submarine melting, which can be a large component of mass loss from both floating tongues 318 and grounded glacier fronts (Rignot et al., 2010; Enderlin & Howat, 2013; Wood et al., 319 2018). Our derivation of Equation 1, which we emphasise is an upper bound on retreat 320 rate, is consistent with high submarine melt that prevents the glacier terminus from ad-321 vancing (see Supplementary Text S4 and Ma, 2018; Ma & Bassis, 2019). However, changes 322 in ocean conditions over time can affect glacier terminus dynamics such that the rate of 323 terminus position change becomes closer to or farther from the theoretical maximum. 324 For example, a decrease in submarine melt rate has been implicated in the recent slow-325 ing of Sermeq Kujalleq's retreat (Khazendar et al., 2019). Future implementations of our 326 method in larger-scale models may therefore benefit from modifications to account for 327 time-varying submarine melt rates. 328

329 5 Conclusions

We have applied a flowline network model of ice dynamics, SERMeQ, to evaluate 330 an upper bound on annual to decadal-scale calving retreat of 155 Greenland outlet glaciers 331 in response to variable climate forcing. Comparison with nearly a decade of terminus po-332 sition records from MEaSUREs (Joughin et al., 2015, updated 2017a) shows that the model 333 bounds retreat rate for 91% of glaciers examined, and that 55% of simulated terminus 334 positions are within twice the observed range. SERMeQ can also evolve upstream sur-335 face elevation with each change in terminus position and compute the resultant loss of 336 ice mass above buoyancy (Supplementary Text S1; Ultee, 2018). The upper bound on 337 retreat rate that we construct with SERMeQ will produce a corresponding high-end es-338 timate of the loss of grounded ice mass, consistent with efforts to find an upper bound 339 on the ice-dynamics contribution to 21st century sea level rise. Our approach is espe-340 cially promising in constraining the dynamic sea level contribution from smaller outlet 341 glaciers that are difficult to resolve in larger-scale continental ice sheet models. 342

343 Acknowledgments

Data on Greenland outlet glacier terminus position and surface ice velocity comes from the MEaSUREs project (Joughin et al., 2015, updated 2017a, 2010, 2015, updated 2017b), available from the National Snow and Ice Data Center. Surface mass balance forcing comes from the HIRHAM regional climate model for Greenland, maintained by the Danish Meteorological Institute and available from http://prudence.dmi.dk/data/temp/RUM/HIRHAM/ GREENLAND/. Python code for data processing (inc. network selection), simulation, and

analysis is maintained in a public GitHub repository, which can be inspected at http://

- 351 github.com/ehultee/plastic-networks. This work is supported by the DOMINOES
- ³⁵² project, a component of the International Thwaites Glacier Collaboration, under National
- Science Foundation grant number AWD005578.

Additional Supporting Information (Files uploaded separately)

 Table S1, a list of all Greenland outlet glaciers in the MEaSUREs dataset with their glacier ID number, name(s), optimal yield strength found, and notes on inclusion in the analysis. The note "Flagged for bad flowline trace" indicates glaciers that required manual intervention to complete data processing, but which are now included in the analysis.

17 Introduction

¹⁸ Text S1. Ice dynamics in SERMeQ

The ice dynamics in our model are based on a perfectly-plastic limiting case of a viscoplastic rheology (Bassis & Ultee, 2019). This rheology describes a glacier with two characteristic timescales: viscous deformation (slow) and mass loss by calving (fast). Modifications to the simple plastic formulation allow calving at a grounded ice-water interface (Ultee & Bassis, 2016) and interaction between multiple tributary glaciers (Ultee & Bassis, 2017). By requiring instantaneous stress balance across the glacier terminus, this formulation finds that the ice thickness H_{terminus} at a given terminus position, in water of depth D, is limited by the yield strength and cannot exceed the yield thickness,

$$H_{\rm y} = 2\frac{\tau_{\rm y}}{\rho_{\rm i}g} + \sqrt{\frac{\rho_{\rm w}}{\rho_{\rm i}}D^2 + 2\frac{\tau_{\rm y}}{\rho_{\rm i}g}},\tag{S1}$$

with τ_y the yield strength of glacier ice, $\rho_i = 920 \text{ kg m}^{-3}$ the density of glacier ice, $\rho_w = 1020 \text{ kg m}^{-3}$ the density of seawater, and $g = 9.81 \text{ m s}^{-2}$ the acceleration due to gravity (Ultee & Bassis, 2016).

In a perfectly plastic glacier (Nye, 1951), the upstream ice thickness H along a central flowline, with along-flow direction x and ice surface elevation s, is also controlled by the yield strength:

$$H\frac{\partial s}{\partial x} = \frac{\tau_{\rm y}}{\rho_{\rm i}g}.\tag{S2}$$

This approximation corresponds to a case where the glacier bed is (nearly) plastic and the glacier stress balance is dominated by shear at the glacier bed and valley walls—appropriate for most Greenland outlet glaciers. We also account for longitudinal

Corresponding author: L. Ultee, ehultee@umich.edu

stresses in a boundary layer near the terminus, where they are more likely to be
 important (Bassis & Ultee, 2019).

Finally, we use mass continuity to derive an expression for the rate of terminus advance or retreat due to calving (see Text S2, below). With each change in terminus position, we calculate a new surface profile according to Equations S1-S2, and we integrate the changes in ice volume above buoyancy throughout the catchment to deduce a contribution to global mean sea level. Figure S1 shows an example sequence of glacier profiles and corresponding sea level contribution as calculated by SERMeQ.

Figure S1. Surface profiles produced by SERMeQ along a flowline in the central part of Ser-33 meq Kujalleq's catchment, with corresponding cumulative sea level contribution (SLE) below. 34 Profiles show glacier ice in grey, bedrock in brown, and fjord water in blue. Spatial scale is in-35 dicated on the 2006 panel and consistent throughout. Labels on 2012 panel indicate along-flow 36 direction x, ice surface elevation s(x), ice thickness H, terminus ice thickness H_t , and terminus 37 location x=L as used in Equations S1-S6. Cumulative SLE on bottom panel reflects catchment-38 integrated loss of ice volume above buoyancy converted to an equivalent volume of seawater and 39 distributed over the area of the global ocean. 40

⁴¹ Despite the simplicity of the model, preliminary experiments have shown promise
 ⁴² in reproducing both surface elevation profiles and advance/retreat rates of glaciers in
 ⁴³ Alaska and Greenland (Ultee & Bassis, 2016, 2017). However, our model only applies to
 ⁴⁴ grounded glaciers and cannot simulate the dynamics of floating ice tongues or shelves.

45 Text S2. Time evolution of the terminus position

Glacier terminus position in SERMeQ evolves in response to near-terminus stretch ing, bedrock topography, and changes in catchment-wide surface mass balance as
 described in Ultee (2018) and Bassis and Ultee (2019). Below is a brief summary
 derivation of the terminus evolution condition as implemented in SERMeQ code.

Let x = 0 represent the ice divide and x = L the terminus, where L = L(t) is the length of the glacier (labelled in Figure S1). The time derivative dL/dt then represents the change in terminus position over time.

Taking the material derivative of the terminus ice thickness $H = H_y$ (constrained by Equation S1), we find

$$\frac{DH}{Dt}\Big|_{x=L} = \frac{DH_y}{Dt}$$

$$\left[\frac{\partial H}{\partial t} + \frac{dL}{dt}\frac{\partial H}{\partial x}\right]_{x=L} = \frac{\partial H_y}{\partial t} + \frac{dL}{dt}\frac{\partial H_y}{\partial x}$$

$$\frac{\partial H}{\partial t}\Big|_{x=L} = \frac{dL}{dt}\left[\frac{\partial H_y}{\partial x} - \frac{\partial H}{\partial x}\right]_{x=L}.$$
(S3)

Mass continuity requires

$$\frac{\partial H}{\partial t} + \frac{\partial}{\partial x}(HU) = \dot{a} \tag{S4}$$

- where H = H(x,t) is the ice thickness, U = U(x,t) the ice velocity, and $\dot{a} = \dot{a}(x,t)$
- the net ice accumulation rate, for all (x, t).

Substituting equation (S4) into (S3), we find

$$\dot{a} - H\frac{\partial U}{\partial x} - U\frac{\partial H}{\partial x} = \frac{dL}{dt} \left[\frac{\partial H_y}{\partial x} - \frac{\partial H}{\partial x}\right]_{x=L}$$
(S5)

$$\frac{dL}{dt} = \frac{\dot{a} - H\frac{\partial U}{\partial x} - U\frac{\partial H}{\partial x}}{\frac{\partial H_y}{\partial x} - \frac{\partial H}{\partial x}},$$
 (S6)

with all terms of equation (S6) evaluated at x = L, the terminus of the glacier (compare

with Equation 54 of Bassis and Ultee (2019)). With the exception of ice accumulation

Upstream from the terminus, we assume a plastic yielding layer at the bed of the glacier. A perfectly plastic glacier would have a rigid ice plug above the yielding layer, but the perfect plastic approximation is a limiting case of several other rheologies that could be used to describe the slow deformation of ice in a pseudo-plug (e.g. Balmforth et al., 2006). Here we choose to describe the slow deformation of intact ice with the familiar Glen's flow law. At the terminus, as in Ultee and Bassis (2016, 2017), we require a vertical yield surface to describe the more rapid motion of fractured, disarticulated ice as it calves away from the intact glacier. This implies that the effective stress in a region of length δ upstream from the terminus is within ϵ of the yield strength τ_y . Near the terminus, we have

$$\frac{\partial U}{\partial x} = \dot{\varepsilon}_{xx} = A \tau_{xx}^n$$
$$= A \tau_v^n, \tag{S7}$$

where flow law exponent n = 3 and A is the flow rate parameter of Glen's flow law.

rate \dot{a} , all terms are determined by the rheology of ice.

We integrate equation (S4) in x to find

$$\int_{0}^{L} \frac{\partial H}{\partial t} \,\mathrm{d}x + (HU)|_{x=L} = \int_{0}^{L} \dot{a} \,\mathrm{d}x \tag{S8}$$

$$U(x = L) = \frac{1}{H_{\text{terminus}}} \int_0^L \left[\dot{a} - \frac{\partial H}{\partial t} \right] \, \mathrm{d}x,\tag{S9}$$

and by the chain rule $\frac{\partial H}{\partial t} = \frac{\partial H}{\partial L} \frac{dL}{dt}$. Separating the integral in equation (S9) and expanding $\frac{\partial H}{\partial t}$ gives

$$U(x = L) = \frac{\dot{\alpha}L}{H_{\text{terminus}}} - \frac{dL}{dt} \frac{1}{H_{\text{terminus}}} \int_0^L \frac{\partial H}{\partial L} \, \mathrm{d}x, \tag{S10}$$

where $\dot{\alpha} = \frac{1}{L} \int_0^L \dot{a} dx$ is the spatially-averaged ice accumulation rate along the flowline.

We now substitute our expressions (S7, S10) in to equation (S4) and rearrange to find to find

$$\frac{dL}{dt} = \frac{\dot{a} - A\tau_{y}^{3}H_{\text{terminus}} + \frac{\alpha L}{H_{\text{terminus}}}\frac{\partial H}{\partial x}}{\frac{\partial H_{y}}{\partial x} - \frac{\partial H}{\partial x}\left(1 - \frac{1}{H_{\text{terminus}}}\int_{0}^{L}\frac{\partial H}{\partial L}\right)}.$$
(S11)

We implement a discretized version of Equation S11 to describe the time evolution of glacier terminus position in SERMeQ.

⁶² Text S3. The role of adjustable parameters

Yield strength τ_y

60

61

63

For each glacier, we optimize the yield strength τ_y to find the best fit between 64 a reconstructed and observed centerline surface elevation profile. Glaciers with flat-65 ter surface slopes, including those close to flotation, are best fit by lower values of 66 $\tau_{\rm v}$. Steeper surface slopes are better fit by higher values of the yield strength. The 67 optimization procedure is discussed in more detail in Ultee and Bassis (2016). The 68 optimal value of $\tau_{\rm v}$ found for each glacier is listed in Supplementary Table 1. There 69 is no correlation between optimal yield strength and glacier latitude, and no other 70 spatial pattern is evident. 71

Figure S2 shows a histogram of the best-fit values of τ_y obtained for the Greenland outlets we simulated. A central peak in the distribution shows that approximately 1/3 of the glaciers we simulate have an optimal yield strength between 125 kPa and 150 kPa. A smaller peak shows that there are also several glaciers in our set best fit by yield strengths between 5 kPa-25 kPa.

In this work, we have used a single value of τ_y at both the ice-bed interface and the calving front. It is plausible that the ice-bed interface could be deforming more readily than the pure ice at the calving front, for example if the glacier bed is composed of saturated marine sediments or if the ice is very close to flotation. Such a case would lead to low ice surface slopes and a low optimal value of τ_y , even though pure ice throughout the glacier may be stronger. We discuss the case of $\tau_{bed} < \tau_{ice}$ in Bassis and Ultee (2019).

$_{85}$ Ice temperature T

The ice temperature T is used to select an appropriate value of the flow-rate parameter A in Glen's flow law. Here, we use an ice temperature constant in space and time and do not optimize for its value. In our previous work, we have found that warmer ice $(T = -2^{\circ} \text{ C})$ is softer and more prone to rapid retreat. Conversely, colder ice $(T = -30^{\circ} \text{ C})$ is stiffer and retreats more slowly. For more details, we refer the interested reader to Ultee (2018).

Figure S2. Histogram of optimal yield strength value found for each glacier.

⁹² Text S4. Inclusion of submarine melt

72

We do not explicitly simulate loss of ice from glacier termini by submarine melting. Rather, we have constructed an upper-bound estimate of retreat that is consistent with high submarine melt rates. Our requirement that effective stress near the glacier terminus must equal the yield strength of ice (see Text S1) makes an implicit constraint on the submarine melt rate, because the rate of submarine melt shapes the stress field near glacier termini (Ma, 2018; Ma & Bassis, 2019). There are three cases to consider:

- ⁹⁹ **Case I** The submarine melt rate is very small compared with the terminus velocity, ¹⁰⁰ $u_s \ll u_t$. In this case, the terminus would be able to advance and thin episod-¹⁰¹ ically. However, advance and thinning would lower the effective stress at the ¹⁰² glacier terminus, such that it would fall below the yield strength of ice and no ¹⁰³ longer satisfy our criterion. We therefore disallow Case I.
- ¹⁰⁴ **Case II** The submarine melt rate is comparable to the terminus velocity, $u_s \sim u_t$. In ¹⁰⁵ this case submarine melt would balance the tendency of ice near the terminus to ¹⁰⁶ stretch and thin, maintaining the terminus ice thickness at the yield thickness.
- 107Case III The submarine melt rate is very large compared with the terminus velocity,108 $u_s \gg u_t$. In this case, the erosion of the terminus by high submarine melt would109create an overhang and promote calving (Ma & Bassis, 2019). Considered at110long enough time scales, e.g. the 0.25 annum standard time step in SERMeQ111rather than the hours to days considered in finer-scale process models, high112submarine melting and enhanced calving would also maintain the terminus ice113thickness.
- Both Cases II and III are consistent with our assumption that there is a yielding boundary layer at the glacier front that constrains the terminus ice thickness (see Bassis & Ultee, 2019). The maximum rate of length change computed in Equation 1 is compatible with both cases, and the ice mass lost in each time step can be considered a combination of mass lost to calving and to submarine melting.

The upper-bound retreat rate that we have sought in this work does not require explicit simulation of the submarine melt rate. Nevertheless, future adaptations of

Figure S3. Network of flowlines on Kangerlussuaq Glacier, MEaSUREs Glacier ID 153, as
 defined with our tracing and filtering algorithm.

our method to simulate calving in larger-scale models may seek to add a mechanism for forcing by time-varying submarine melt. We suggest that those efforts begin by allowing submarine melt rate u_s to modify the terminus velocity, U in Equation 1, with the understanding that doing so may introduce scenarios that are incompatible with our original assumptions.

126 Text S5. Flowline network selection

We apply our depth-integrated, width-averaged model on a network of interacting 127 glacier flowlines, as described in Ultee and Bassis (2017). Previous applications have 128 used flowlines selected by hand (Ultee & Bassis, 2016; Ultee, 2018) or by an automated 129 method that detects valley walls of mountain glacier networks (Kienholz et al., 2014; 130 Ultee & Bassis, 2017). Neither method is suitable for the hundreds of Greenland 131 outlet glaciers we consider here. It is impractical to select hundreds of flowlines by 132 hand, and outlets of the Greenland Ice Sheet, unlike mountain glaciers, expand to a 133 nearly featureless catchment upstream with no valley walls to aid in flowline selection. 134 We therefore apply a new selection algorithm based on tracing ice surface velocity. 135

We begin with a surface velocity composite covering the entire ice sheet (ENVEO, 138 2017). For each glacier included in the MEaSUREs dataset (Joughin et al., 2015, up-139 dated 2017), we extract all points observed along the 2006 terminus position. We then 140 trace each point up the surface velocity field until a pre-determined minimum velocity 141 cutoff (identical for all glaciers); our viscoplastic approximation is most suitable near 142 the glacier terminus (Ultee & Bassis, 2017; Bassis & Ultee, 2019), so we do not extend 143 our simulated catchments all the way to the ice divide. Finally, we filter the set of 144 full-length flowlines so that the most central flowline is defined as the "main trunk". 145 The parallel portions of the remaining flowlines are trimmed and network intersec-146 tions defined where the angle between flowlines exceeds a threshold value (identical 147 for all glaciers). The code used in network selection is available in our public GitHub 148 repository, and an example network is shown in Figure S3. 149

The tracing and filtering of flowlines from surface velocity is prone to error where the velocity dataset is noisy or includes holes. Errors in flowline tracing generally become apparent in later data-processing steps, for example if no optimal yield strength value can be found. Networks affected by such errors include the note "Flagged for
 bad flowline trace" in Table S1.

¹⁵⁵ Text S6. Detailed case studies

As described in the main article text, 40% of terminus positions simulated by 156 SERMeQ fall within the range of observed terminus position for the same year. Be-157 cause SERMeQ is sensitive to bed topography features (Ultee, 2018) and is forced by 158 climate reanalysis data, model performance will generally be best where those data 159 products are most accurate. The agreement between modelled and observed retreat 160 of Sermeq Kujalleq (glacier ID 3, also called Jakobshavn Isbræ, main text Figure 3c), 161 where bed topography has been especially well examined by previous glaciological 162 studies, illustrates this point. 163

It is our aim to produce an upper bound on outlet glacier retreat and associated 164 mass loss. We demonstrated in Bassis and Ultee (2019) that Equation 1 is a theoretical 165 bound on the rate of calving retreat. Thus, we anticipate that the rate of retreat 166 simulated by SERMeQ will generally exceed the observed rate of retreat. To support 167 future implementation of this calving-rate bound in our model or others, it is important 168 to understand where it does not perform as expected. There are two cases to consider: 169 (1) the retreat rate simulated by SERMeQ is slower than the rate observed, or (2) the 170 retreat rate simulated by SERMeQ far exceeds the rate observed (by a factor of 5 or 171 more). We describe three illustrative examples here. 172

¹⁷³ Mean simulated retreat slower than observed

Main text Figure 3a shows the simulated and observed changes in length for 174 Apuseeq Anittangasikkaajuk (MEaSUREs Glacier ID 137), a small outlet glacier on 175 the east coast of Greenland. Our analysis shows that the mean rate of simulated 176 (single point) terminus retreat was 31 m/a, while the mean observed rate of retreat 177 of the terminus centroid was 87 m/a. This is one of only a handful of cases in which 178 the mean observed rate over the 2006-2014 period exceeds the supposed upper-bound 179 rate produced by Equation 1. However, in this case both rates are small, and the 180 simulated terminus position remains within the observed range of terminus positions. 181 We also note that Apuseeq Anittangasikkaajuk is seldom included in other studies of 182 Greenland outlets; as such, the quality of bed topography and climate data for this 183 outlet may be relatively lower. 184

185 Mean simulated rate far exceeds observed

Main text Figure 3b shows the simulated and observed changes in length for Helheim Glacier (MEaSUREs Glacier ID 175), a large and well-studied outlet in southeast Greenland. The data quality for this outlet should be comparatively high. Nevertheless, SERMeQ simulates a mean retreat rate of 1980 m/a, which far exceeds the mean observed retreat rate of 313 m/a. We attribute this rapid retreat to features in the bed topography, combined with the no-flotation condition we have implemented in SERMeQ.

The terminus of Helheim Glacier has been observed to float in some years, and 193 was likely floating at the beginning of our simulation period according to bed and 194 surface topography from Morlighem et al. (2017). The glacier bed is more than 600 195 m below sea level and retrograde for several kilometers upstream of the present ter-196 minus, as shown in Figure S4. As explained in main text section 2 and in Ultee and 197 Bassis (2016, 2017), SERMeQ does not allow floating ice tongues to form. Where 198 small tongues are present, we remove them and simulate the first grounded point as 199 the "terminus". In the case of Helheim Glacier, when we removed floating ice, the 200

Figure S4. Near-terminus bed topography of Helheim Glacier. Brown filled region shows glacier bed and grey filled region shows glacier ice, both from Morlighem et al. (2017). Note 10:1 exaggeration in vertical scale. A red overlay indicates floating ice that was removed in our simulation. Annotation at figure left indicates the ice surface elevation at the terminus as recorded in Morlighem et al. (2017), further evidence that the initial terminus could not have been grounded ice.

simulated terminus was pushed onto the retrograde bed, where it began an unstable
retreat. In summary, the true near-terminus dynamics and stress field of Helheim
Glacier are shaped by the presence of floating ice that interacts with the fjord walls.
SERMeQ does not include these dynamics and therefore simulates an upper-bound
retreat that could occur in the absence of floating ice.

Successive under- and over-estimates within observed period

In a handful of other cases, the rate of retreat observed during a short period 213 exceeds the rate simulated during the same period. Underestimated retreat in one 214 time period is nearly always coupled with overestimated retreat in another period, 215 such that the aggregate effect over the course of the simulation remains an upper-216 bound estimate of net retreat. For example, between 2007 and 2008, the floating ice 217 tongue of Hagen Brae (MEaSUREs Glacier ID 105) disintegrated (Solgaard et al., 218 2020). The resulting observed rate of retreat, more than 10 km/a, far exceeded the 219 rate simulated by SERMeQ (< 1 km/a) over the same period (Figure S4). However, 220 our model initialization had already removed the floating portion of the glacier as 221 of 2006, so the SERMeQ-simulated terminus position was still more retreated than 222 the observed. In the subsequent period between 2008 and 2012, SERMeQ slightly 223 overestimated the observed retreat rate. Figure S5 illustrates this history. In Figure 224 S6, we have annotated the floating ice removed upon initialization, the collapse of 225 which was responsible for anomalously high observed retreat between 2007 and 2008. 226
