Abstract

While the notion that injecting fluids into the subsurface can reactivate faults by reducing frictional resistance is well established, the ensuing evolution of slip is still poorly understood. What controls whether the induced slip remains stable and confined to the fluid-affected zone or accelerates into a runaway earthquake? Are there observable indicators of the propensity to earthquakes before they happen? Here, we investigate these questions by modeling a unique fluid-injection experiment on a natural fault with laboratory-derived friction laws. We show that a range of fault models with diverging stability with sustained injection reproduce the slip measured during pressurization. Upon depressurization, however, the most unstable scenario departs from the observations, suggesting that the fault is relatively stable. The models could be further distinguished with optimized depressurization tests or spatially distributed monitoring. Our findings indicate that avoiding injection near low-residual-friction faults and depressurizing upon slip acceleration could help prevent large-scale earthquakes.

Constraining Fault Friction and Stability with Fluid-Injection Field Experiments

Key Points:

- Multiple frictional models with different stability reproduce the slip observed during the pressurization stage of a field experiment
- The depressurization phase provides additional constraints on hydromechanical parameters and hence fault stability
- Fault stability and the spatial extent of slip relative to the pressurized region depend on residual friction vs initial stress levels

Abstract

While the notion that injecting fluids into the subsurface can reactivate faults by reducing frictional resistance is well established, the ensuing evolution of slip is still poorly understood. What controls whether the induced slip remains stable and confined to the fluid-affected zone or accelerates into a runaway earthquake? Are there observable indicators of the propensity to earthquakes before they happen? Here, we investigate these questions by modeling a unique fluid-injection experiment on a natural fault with laboratory-derived friction laws. We show that a range of fault models with diverging stability with sustained injection reproduce the slip measured during pressurization. Upon depressurization, however, the most unstable scenario departs from the observations, suggesting that the fault is relatively stable. The models could be further distinguished with optimized depressurization tests or spatially distributed monitoring. Our findings indicate that avoiding injection near low-residual-friction faults and depressurizing upon slip acceleration could help prevent large-scale earthquakes.

Plain Language Summary

Fluid injections into the Earth's crust are common practice in the exploitation of subsurface energy resources such as geothermal energy, shale gas and conventional hydrocarbons. These injections can perturb nearby fault structures and hence induce earthquakes and transient slow slip. Understanding what controls the stability (i.e., the propensity to generate earthquakes) and spatial extent of the fault response as well as identifying precarious faults is crucial to minimize the seismic hazard associated with these industrial practices. Here, we take a step towards this goal by modeling a unique experiment in which water was injected into a natural fault and the resulting slip measured directly at depth. We first show that multiple models

can explain the observations equally well while pressure is increased in the experiment. In these models, how stable the fault response is with further injection and how large of a zone is reactivated compared to the fluid-affected region depends on frictional properties. We then demonstrate that the slow slip response to a decrease in injection pressure further constrains the range of admissible models. Our work suggests that it may be possible to identify potentially hazardous faults with optimally designed injection tests without inducing damaging earthquakes.

1 Introduction

Earthquakes induced by fluid injection into the subsurface pose a major challenge for the geoenery industry and society in general (Ellsworth, 2013; Grigoli et al., 2017). Tectonically-quiet regions where dormant faults could be reactivated are particularly challenging, as their infrastructure is often not designed for large-magnitude induced earthquakes (McGarr et al., 2015). At the same time, some faults have been observed to slip stably at aseismic speeds of 10^{-7} – 10^{-2} m/s in response to fluid injection (Cornet et al., 1997; Duboeuf et al., 2017; Guglielmi et al., 2015; Scotti & Cornet, 1994; Wei et al., 2015). While induced earthquakes have been located anywhere from a few meters to tens of kilometers from injection wells (Goebel & Brodsky, 2018), the spatial extent of fluid-induced aseismic slip is not as well characterized due to the paucity of direct observations. Understanding what conditions lead to seismic versus aseismic and localized versus widespread fault reactivation is central to physics-based hazard forecasting.

An outstanding opportunity to investigate these questions is offered by a decametric-scale fluid injection experiment recently conducted in an underground tunnel intercepting a dormant fault in a carbonate formation (Guglielmi et al., 2015) (Figure 1A). During the experiment, the fluid pressure and fault slip were recorded at the injection site. Although the observed slip was

mostly aseismic, it is important to understand if the observations contained sufficient information to determine whether slip would have accelerated into an earthquake rupture if injection had continued. Previous efforts to model the field experiment with a slip-weakening friction law concluded that aseismic slip outgrew the pressurized zone, potentially leading to a runaway earthquake with continued injection (Bhattacharya & Viesca, 2019).

Here, we use the data from the field experiment to examine the issue of slow and confined vs. fast and runaway slip in models with more realistic, laboratory-derived rate-and-state friction laws (Dieterich, 1979, 2007; Ruina, 1983) consistent with laboratory results on materials from this specific fault zone (Cappa et al., 2019). Furthermore, we use the modeling to identify promising avenues to quantify the fault properties and control injection-induced seismicity hazard. We adopt a fully-dynamic computational framework that resolves both aseismic and seismic slip on faults. We keep other model ingredients relatively simple to better understand frictional effects in the presence of a diffusing fluid. For example, we do not explicitly model the change in fault permeability induced by slip as in previous studies (Bhattacharya & Viesca, 2019; Cappa et al., 2019; Guglielmi et al., 2015). Nonetheless, we find that multiple frictional scenarios of varying spatial behavior and proneness to large earthquakes match the slip observations of the field experiment equally well during fault pressurization. We also find that depressurization provides further constraints that could help identify potentially hazardous faults.

2 Data and Methods

2.1 A unique fluid-injection experiment on a natural fault

The unprecedented field experiment involved injecting water directly into the fault zone and measuring the resulting fault slip at a depth of 280 m with a specially designed borehole probe (Guglielmi et al., 2015) (Figure 1A). Prior to the experiment, the shear and normal stress acting on the fault were estimated at 1.65 ± 0.5 and 4.25 ± 0.5 MPa, and the permeability and bulk modulus of the initially dry fault at 7×10^{-12} m² and 13.5 ± 3.5 GPa, respectively. Figure 1B summarizes the main observations of the experiment, including the deceleration of slip associated with depressurization not discussed in previous works. The slip measured during the pressurization phase displays three distinct slip stages. At first, the fault is inactive and no significant slip is recorded. The second stage initiates between 300 and 400 s when slip rates attain $\sim 10^{-7}$ m/s and the accumulated slip becomes measurable within the timeframe of the experiment. Stage 3 corresponds to the sharp acceleration to slip velocities of $\sim 10^{-6}$ m/s without any significant increase in injection pressure at ~ 1200 s. Hydromechanical modeling suggests that 70% of the 20-fold increase in permeability during the experiment occurred prior to this acceleration (Guglielmi et al., 2015). Laboratory experiments were also performed on grinded materials from the fault zone to further constrain the rate-and-state frictional properties (Cappa et al., 2019).

2.2 Diffusion of pore fluid pressure into the fault zone

We model the field experiment as a fluid injection into a planar fault embedded in an elastic medium (Figure 1AC). We simulate the fluid injection by prescribing an evolution of pore pressure at the center of the fault that approximates the pressure history of the field experiment (Figure 1B, top). Simulations with a smooth pressure evolution result in similar but easier to interpret simulation results than those with the exact pressure history (Figures S1-S2).

The imposed pressure diffuses axisymmetrically into the fault plane as follows:

$$\frac{\partial p(r, t)}{\partial t} = \alpha \left(\frac{\partial^2 p(r, t)}{\partial r^2} + \frac{1}{r} \frac{\partial p(r, t)}{\partial r} \right) \quad (1)$$

where p is the pore pressure, r is the radial distance from the injection interval, t is time, and α is the hydraulic diffusivity. The diffusion is numerically implemented using a forward finite difference scheme. Injection pressure is prescribed at a distance of $r_{inj} = 0.05$ m from the center of the fault to mimic the experimental procedure. Although we prescribe zero pressure boundary conditions to emulate the initially dry fault, the choice of boundary condition is not essential here because the size of the simulated fault (250 m) is larger than that of the pressure diffusion. Models with larger fault domains produce nearly identical results (Figure S3).

Although both pressure and flow rate are reported as part of the field experiment, the exact value of the hydraulic diffusivity α is still uncertain because the spatial extent of the pressurized zone and the fault thickness over which the diffusion occurs, b , are poorly constrained. The volumetric flow rate, Q , depends on b as:

$$Q = - \frac{kb(2\pi r_{inj})}{\eta} \frac{\partial p}{\partial x} \quad (2)$$

where k is the permeability of the fault zone, r_{inj} is the injection radius and η the dynamic viscosity of water. Hence, for a given flow rate, there is a trade-off between the fault thickness b over which the fluid diffusion occurs and the permeability k (and hence hydraulic diffusivity $\alpha = \frac{k\rho g}{\eta S_S}$, where S_S is the specific storage) of the fault zone. In Section 3, we use hydraulic diffusivities of 0.04, 0.20, and 0.85 m²/s to match field experimental measurements of slip for different friction regimes. Assuming the specific storage of $S_S = 2 \times 10^{-4}$ m⁻¹ as in Bhattacharya and Viesca (2019), these hydraulic diffusivities correspond to the permeability values of 0.8, 4, and 17×10^{-12} m² that are within the ranges presented in previous studies that considered

permeability enhancement: 0.8 to $1.3 \times 10^{-12} \text{ m}^2$ (Bhattacharya and Viesca, 2019) and 7 to $100 \times 10^{-12} \text{ m}^2$ (Guglielmi et al., 2015). These permeability values are also consistent with the flow rates measured in the field experiment, for reasonable values of the fault thickness b of 29 , 6.7 , and 1.8 cm , respectively (Figure 1B). While considering permeability enhancement may be necessary to match the finer features of the pressure and flow rate histories (unless the fault thickness b affected by fluid flow varies with time or with space), all three combinations of the parameters we use reproduce the hydrologic observations to the first order. We therefore consider a range of constant hydraulic diffusivity (and hence permeability) values in our search for models that reproduce the main features of the experimental observations.

2.3 Numerical modeling of fluid-induced fault slip

As fluid pressure increases and diffuses into the fault plane, fault friction eventually decreases and measurable slip ensues (Figure 1C). We model this induced fault slip using a fully-dynamic 2D antiplane boundary integral method capable of simulating the complete seismic cycle including both aseismic and seismic deformation (Lapusta et al., 2000; Noda & Lapusta, 2013). Fault slip is governed by the following elastodynamic equation:

$$\tau(x, t) = f[\sigma - p(x, t)] = \tau_{ini} + F[\delta(x, t)] - \frac{\mu}{2c_s} V(x, t) \quad (3)$$

where τ is the shear stress, f the friction coefficient, σ the normal stress, τ_{ini} the initial (i.e., background) shear stress, F a linear functional which depends on the slip history, δ , μ the shear modulus of the elastic medium, c_s the shear wave speed and V the slip rate. The friction coefficient in (3) follows an empirical rate-and-state formulation derived from laboratory experiments which describes the dependence of f on the slip rate and a state variable θ (Dieterich, 1979, 2007; Ruina, 1983):

$$f(V, \theta) = f^* + a \ln \frac{V}{V^*} + b \ln \frac{V^* \theta}{D_{RS}} \quad (4)$$

where a and b are the direct and evolutionary rate-and-state parameters, D_{RS} is the critical slip distance and f^* is a reference coefficient of friction at reference slip rate V^* . The state variable is assumed to evolve according to the aging law (Marone, 1998; Ruina, 1983).

As the fault in the experiment is inactive prior to the fluid stimulation, the modeled fault is not loaded tectonically. Fault slip is thus purely fluid-induced, i.e., no significant slip would occur without the injection within the time scales considered in the simulations. To initialize the models, we impose shear and normal stresses in agreement with the values reported at the field site prior to the experiment (Guglielmi et al., 2015) and initial state variable values consistent with a dormant, highly healed fault (Text S1; Figures S4-S7). The corresponding initial slip rate is then computed from Eq. (4).

3. Results

3.1 Models in agreement with the slip observations during pressurization

By first limiting our analysis to the pressurization stage of the experiment (up to 1400 s), we find that the observations are equally well reproduced by a family of models. Three representative cases, which we denote lower-, intermediate- and higher-friction models, are shown in Figures 2A-C and S8 to S11 and Table S1. Below we explain how we constrained these models by examining how the various parameters govern the transitions between the different slip stages and considering the trade-off between friction and fluid pressure.

At the beginning of all simulations, slip rates are low and both inertial effects and elastic stress transfers are negligible. Eq. (3) then reduces to:

$$f(V, \theta)[\sigma - p(x, t)] = \tau_{ini} \quad (5)$$

As p increases and τ_{ini} remains constant over time, f must increase via growing slip rates in order for (5) to remain true, resulting in a balance between the direct frictional effect and changes in pore pressure (Dublanche, 2019). Slip rate and friction continue increasing until slip becomes significant at $V \sim 10^{-7}$ m/s. The onset of significant slip thus approximately coincides with the maximum friction reached during the simulations (Figures 2AB, S8). The peak friction, f^p , can be approximated as:

$$f^p \sim f^* + a \ln \frac{V_s}{V^*} + b \ln \frac{V^* \theta_{ini}}{D_{RS}} \quad (6)$$

where $V_s = 10^{-7}$ m/s. The state variable remains at its initial value, θ_{ini} , as it has not evolved significantly yet due to negligible slip and short healing time compared to its large initial value. Moreover, because the fluid pressure at the injection site is known at all times, we can relate f^p to the timing of slip initiation, t_s :

$$f^p = \frac{\tau_{ini}}{[\sigma - p(0, t_s)]} \quad (7)$$

It is thus possible to control t_s by computing the corresponding f^p with Eq. (7) and selecting f^* , a , b , θ_{ini} and D_{RS} such that Eq. (6) is satisfied. The three example models have t_s between 300 and 400s and f^p between 0.84 and 0.99 (Figures 2B, S8).

Once significant slip starts accumulating, the fault begins weakening until it reaches steady state and friction reaches its quasi-static residual value of $f^r = f^* + (a - b) \ln V/V^*$ at the latest stage of the fault pressurization experiment (Figure 2B, S8). As in Dublanche (2019)'s rate-strengthening models, we find that this transition to steady state is accompanied with a marked acceleration in slip rate (Phase II in Dublanche, 2019) which we assume to explain the acceleration observed at 1200s.

The critical slip distance, δ_c , over which friction weakens from f^p to f^r can be approximated as:

$$\delta_c \sim \frac{f^p - f^r}{b/D_{RS}} \quad (8)$$

since $\frac{\partial f}{\partial \delta} \sim \frac{b}{D_{RS}}$. Furthermore, from elasticity, slip is related to stress drop by:

$$\Delta \delta \propto \frac{\Delta \tau h}{\mu} \quad (9)$$

where h is the length of the slipping zone. By equating Eq. (8) and (9) at the center of the fault, we can estimate the slipping zone size, h_{ac} , at which steady state is reached and Stage 3 initiates:

$$h_{ac} \propto \frac{\mu D_{RS}}{b} \frac{f^p - f^r}{\Delta \tau} \quad (10)$$

Moreover, by choosing V^* to be on the same order of magnitude as the fastest slip rate measured during the field experiment ($V^* = 10^{-6}$ m/s), we can approximate f^r with f^* since the contribution of $(a - b) \ln V/V^*$ becomes small compared to that of f^* . Eq. (10) can then be rewritten in terms of known parameters as:

$$h_{ac} \propto \frac{\mu D_{RS}}{b} \frac{a \ln \frac{V_s}{V^*} + b \ln \frac{V^* \theta_{ini}}{D_{RS}}}{\tau_{ini} - f^* [\sigma - p(0, t_{ac})]} \quad (11)$$

where t_{ac} denotes the onset of Stage 3. For all the simulations presented in this work, we find that adding a pre-factor of 3 to Eq. (11) provides a good estimate of the slipping zone size at t_{ac} (Text S2). Remarkably, h_{ac} only depends on quantities at the injection site. We can thus control the initiation of Stage 3 in our simulations by tuning the model parameters such that the slipping zone reaches length h_{ac} at ~ 1200 s as is the case for our three representative models in Figure 3.

Another critical aspect in these simulations is the balance between friction and the pore pressure forcing. Figures S20-S23 illustrate how the aseismic slip zone grows with decreasing

f^* and increasing α , respectively. In particular, during Stage 3, the spatial extent of the slipping zone with respect to the pressurized zone and the slip rate at the injection site depend on the difference between the residual and initial friction, $f^r - f_{ini}$, which controls the elastic energy available to drive fault rupture once initiated (Bhattacharya & Viesca, 2019; Dublanche, 2019; Galis et al., 2017; Garagash & Germanovich, 2012) (Figure S19A-C). Note that this is distinct from the difference between peak and initial friction, $f^p - f_{ini}$ (e.g., Gischig, 2015), which controls the timing of fault reactivation as discussed above.

Given all these consideration, for each diffusion scenario presented in Figure 1B, we find a corresponding frictional model by adjusting f^* such that the simulated slip matches the observations during the first 2 slip stages and produces a sufficiently large slip transient during Stage 3. To be able to use f^* values in agreement with the range $f^r = 0.55 - 0.65$ inferred from laboratory experiments on the grinded fault zone material (Cappa et al., 2019), we set f_{ini} to 0.54 ($\tau_{ini} = 2.15$ MPa, $\sigma = 4.00$ MPa), which is within the uncertainty range of the initial stress measurements. The selected values of f^* restrict the range of possible values for the term $b \ln V^* \theta_{ini} / D_{RS}$ in Eq. (6) in order for slip to initiate between 300 and 400 s, which in turn restricts factor $\mu D_{RS} / b$ in Eq. (11) in order for Stage 3 to initiates at 1200s. The factor μD_{RS} which appears in estimates of critical nucleation lengths also needs to be large enough to avoid nucleation of dynamic events within the experimental time (e.g., Rice & Ruina, 1983; Rubin & Ampuero, 2005). Finally, we fine tune parameters a and θ_{ini} to adjust the slope and timing of the acceleration, respectively. Note that decreasing a while keeping b constant increases the slope of the slip acceleration - due to the (weak) dependence of f^r on $(a - b)$ - and eventually leads to the nucleation of a dynamic event right at t_{ac} (Figure S16 and S19D-F). This procedure results in a family of models with $f^* = 0.48$ to 0.60 , $a - b = -0.001$ to -0.005 ($b = 0.016$), $\theta_{ini} = 1.2 \times 10^{12}$

to 7.0×10^{12} s and $\alpha = 0.04$ to 0.85 m²/s that match the slip observations equally well during pressurization.

Although the three models exhibit comparable slip histories at the injection site, they differ in features that were not directly accessible to field observation. In particular, their spatial behaviors differ qualitatively (Figure 3, S9-S11). Defining the pressurized zone with 0.5 MPa pressure contours as in previous works, the lower-friction scenario produces an aseismic front that outruns the pressurized region, within 1400 s, as in slip-weakening models (Bhattacharya & Viesca, 2019) (Figure 3D). By contrast, in the higher-friction model, which reproduces the observations equally well, aseismic slip remains confined well within the pressurized area (Figure 3F). Our models demonstrate that slip did not necessarily extend beyond the pressure perturbation during the experiment; that explaining a slip history at a single point in space is a non-unique problem; and that further hydro-mechanical complexity is not required to explain the observed slip to first order. Monitoring fault slip and fluid pressure along the length of the fault, directly with additional probes or remotely with geophysical methods, would help distinguish between these different scenarios and would allow to study additional fault processes such as permeability evolution and inelastic dilatancy (Segall & Rice, 1995).

3.2 Distinguishing between models with depressurization

We find that the depressurization stage of the field experiment, which was not discussed or modeled in previous studies (Bhattacharya & Viesca, 2019; Cappa et al., 2019; Derode et al., 2015; Guglielmi et al., 2015), contains valuable information on fault properties. In this pressure-reduction stage, the lower-friction model features a pronounced delayed slip response that is not observed in the experiment or in the other two cases (Figure 2A). The intermediate- and higher-friction models, which also have higher hydraulic diffusivities, thus explain the entire set of

observations better than the lower-friction model. Further discriminating between these two models is not possible with the current dataset because, by the time depressurization is initiated, the slip rates in these simulations are too low to produce a detectable difference in incremental slip. However, if the injection pressure is decreased more gradually and earlier in the acceleration phase – at which point the intermediate- and higher-friction scenarios have approximately the same (and higher) slip rate – the three scenarios lead to diverging levels of incremental slip (Figure 2D). As we only investigate a limited portion of the rate-and-state parameter space in this study, we cannot conclude that timely depressurization can uniquely discriminate between all possible frictional scenarios. However, it is clear that timely depressurization can provide additional constraints on the frictional and hydromechanical properties of fault zones.

In addition to fitting the entire set of slip observations better, models with f^* of 0.55 and 0.60 are also more consistent with the range of residual friction values of 0.55 to 0.65 derived from laboratory experiments on grinded fault gouge (Cappa et al., 2019). Moreover, the initial fault conditions implied by these higher-friction cases are fully consistent with those of a dormant fault whereas the low-friction case is not (Text S1). Our preferred model for the site of the injection experiment is thus a rate-weakening fault with $0.55 < f^* < 0.60$, $0.20 < \alpha < 0.85$ m²/s, $a = 0.011$ and $b = 0.016$. This is in contrast to the original Guglielmi et al. (2015) study in which the authors inferred a rate-strengthening fault from a spring-slider model with permeability enhancement. Within the limited parameter space that we explored through the procedure outlined in section 3.1, we could only find rate-strengthening models with relatively low f^* and hence ones that only match the pressurization stage of the experiment (Figure S24). It is possible that there are 2D models with rate-strengthening parameters that match the entire slip

history that we have not considered here, which would further strengthen our conclusions that the field measurements can be matched with multiple friction scenarios and that the depressurization stage provides further constraints than pressurization alone.

3.3 Diverging fault stability with sustained injection

Modeling what would have happened if the fluid injection had continued for longer highlights why distinguishing between the three qualitatively different scenarios identified in this study is crucial. In response to an extended constant-pressure injection (Figure 4, Figures S3, S25-S27), the low-friction fault nucleates an earthquake almost immediately, while the intermediate and higher-friction faults decelerate and continue slipping aseismically before eventually transitioning to seismic slip rates. Once a seismic rupture initiates, whether it is self-arrested or run-away depends on the *dynamic* residual friction, f^d , which is generally slightly lower than f^r (Galis et al., 2017; Garagash & Germanovich, 2012). If $f^d < f_{ini}$, as in the low- and intermediate-friction cases (Figure 4B), the rupture may release enough elastic energy to propagate beyond the fluid-affected regions and would only be stopped by less favorably stressed fault patches, geometrical barriers, or more stable materials not present in the current model (Figures 4C,D). Such runaway ruptures may be preceded by smaller ruptures or aseismic slip transients (Figures S15 and S19A); indeed, in fracture mechanics models (Galis et al., 2017), the transition to runaway rupture requires a certain balance between fluid pressurization and background stress to be reached. If $f^d < f_{ini}$, as in the high-friction case, the rupture self-arrests once out of the pressurized zone (Figure 4E). For low- to intermediate-friction faults, the maximum expected earthquake magnitude, M_{max} , is thus controlled by hydro-mechanical and geometrical fault properties as opposed to injection attributes (e.g., cumulative volume injected) (van der Elst et al., 2016; Galis et al., 2017; Gischig, 2015; McGarr, 2014). For example, varying

the injection rate in our simulations does not alter the event size (Figure S28). In the intermediate-friction case, the fault ultimately undergoes a runaway earthquake despite having stably released energy for over an hour, thus demonstrating that aseismic slip does not signify an absence of earthquake hazard. Fortunately, comparing the depressurization and prolonged injection scenarios reveals that reducing the injection pressure might be sufficient to suppress earthquake nucleation at the injection site. The lower the friction on the fault, the faster the rate of this depressurization needs to be (Figure S29). Note, however, that earthquakes could still be triggered by aseismic slip itself on more unstable heterogeneities away from the injection site (Eyre et al., 2019; Guglielmi et al., 2015).

4 Discussion and Conclusions

To summarize, our modeling of a fluid-injection experiment into a fault zone reveals that the difference between fault prestress and quasi-static or dynamic fault friction controls whether slip is confined to the fluid-affected zone or outruns it. We find that: (i) multiple scenarios with different hydrologic assumptions and friction levels are consistent with the measured slip at the injection site during the pressurization phase, (ii) the low-friction scenario in which slow slip outruns the pressurized region is inconsistent with slip during the depressurization phase, and (iii) the high-friction scenario, in which the slipping zone is well confined within the pressurized region, is most consistent with the full range of information from the experiment, including the fault behavior during fault depressurization and laboratory friction measurements on the materials from the fault zone. Key hydro-mechanical parameters such as the difference between quasi-static friction and initial normalized prestress, $f^r - f_{ini}$, the rate dependence of friction, $a - b$, and the hydraulic diffusivity, α , exercise a first-order control on the stability and spatial extent of a fault response to fluid injections. Further constraining these parameters is thus critical

for seismic hazard management. In the geoenergy industry, test injections with timely depressurization and spatiotemporal monitoring of fluid pressure and aseismic slip could be performed prior to exploitation to ensure that there are no low-friction faults nearby. Our findings show that augmenting fault-pressurization experiments with suitably designed depressurization phases and multiple monitoring locations along the fault could provide invaluable insight into the physics of both induced and natural earthquakes (Savage et al., 2017) and friction properties of dormant faults. Such more advanced injection experiments and corresponding modeling work will potentially be able to assess the effects and relative importance of additional mechanisms (e.g., poroelastic stresses (Deng et al., 2016; Goebel et al., 2017; Segall & Lu, 2015), slip-induced dilatancy (Cappa et al., 2019; Segall & Rice, 1995), bulk fluid diffusion, and enhanced dynamic weakening) and complexity (e.g., material heterogeneities (Eyre et al., 2019)).

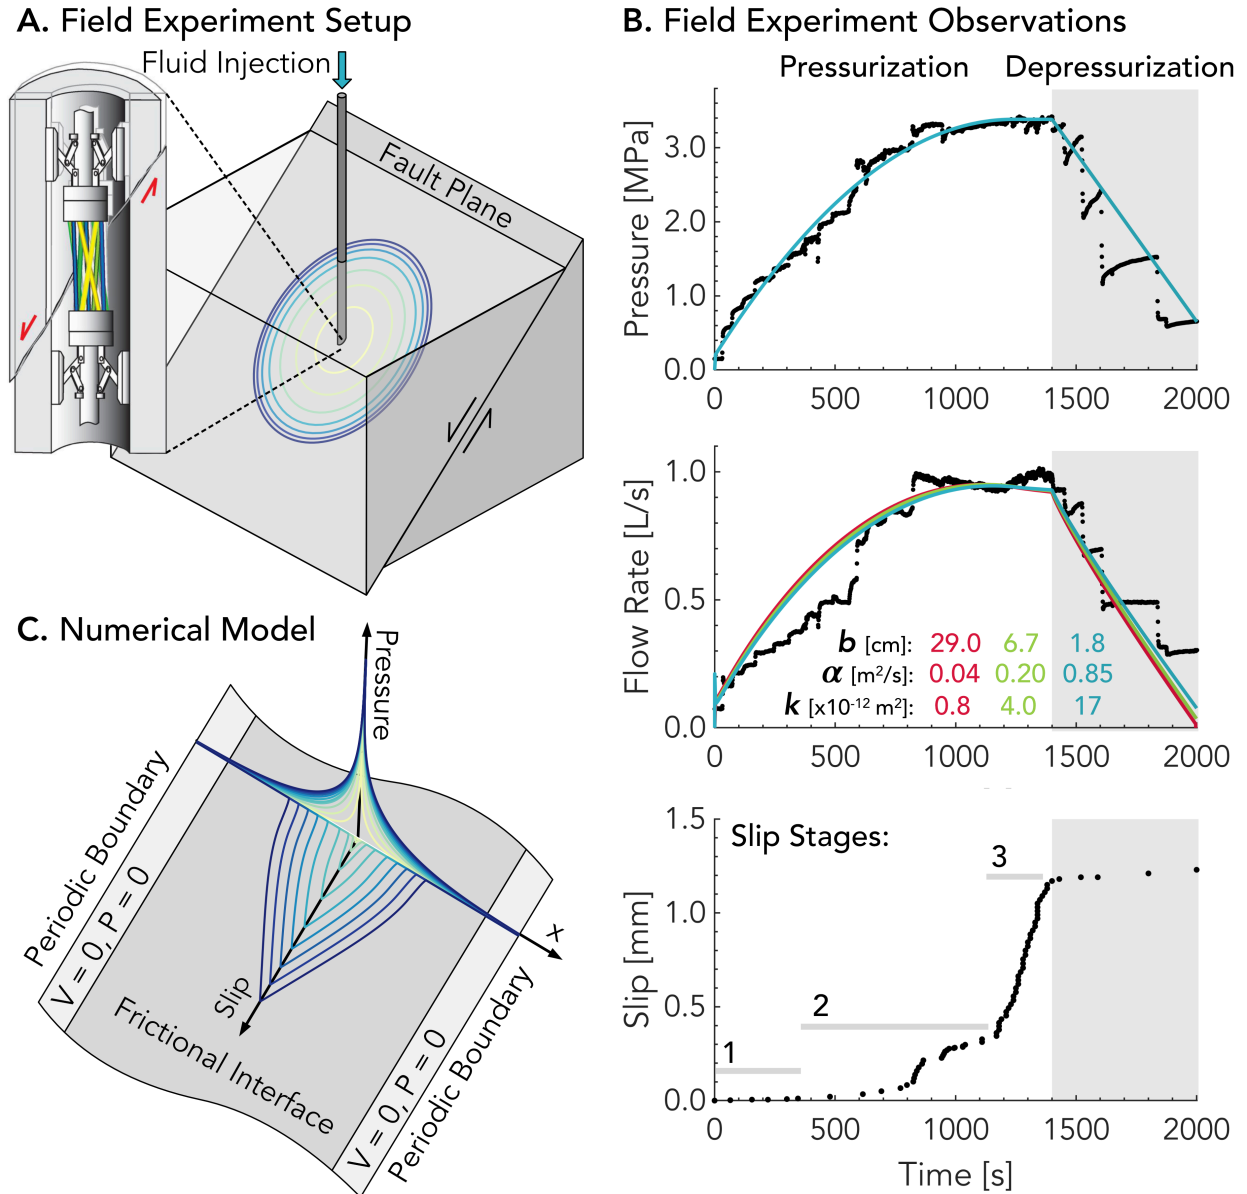

Figure 1. In situ measurement and modeling of fault slip induced by fluid injection. (A) Schematic of the field experiment presented in Guglielmi et al. (2015) in which fluid injected into a borehole crossing a natural but inactive fault caused its reactivation. A special borehole probe (SIMFIP) was used to measure the fault displacements directly at the injection site. **(B)** Pressure, flow rate, and fault slip measured during the field experiment. The colored lines and associated parameters correspond to the three different hydrological models considered in this study. The grey area indicates the depressurization stage that has not been shown nor modeled in prior studies. **(C)** Schematic of the model used to simulate slip on a fault plane embedded in an elastic bulk medium. Snapshots of a sample fluid pressure diffusion scenario and its resulting fault slip are shown for illustration (the darker colors indicate later times). Schematics **(A)** and **(C)** are not to scale.

Figure 2. Multiple simulated scenarios match the pressurization stage of the experiment but respond differently to depressurization. (A) Temporal evolution of pore fluid pressure, slip and slip rate for three model scenarios (solid curves) that reproduce the observations (black dots) during the field-experiment pressurization. (B) Simulated evolution of friction with slip at the injection site; the three scenarios correspond to lower (red), intermediate (green), and higher (blue) residual friction in comparison to the fault prestress (black dashed line). Note that only the intermediate and higher-friction faults result in slip consistent with the depressurization part. (C) Key frictional and hydraulic properties of the three scenarios. (D) Similar to (A) but for an improved depressurization: Reducing injection pressure once slip starts to accelerate would allow to distinguish between all three cases, helping to constrain the fault friction properties.

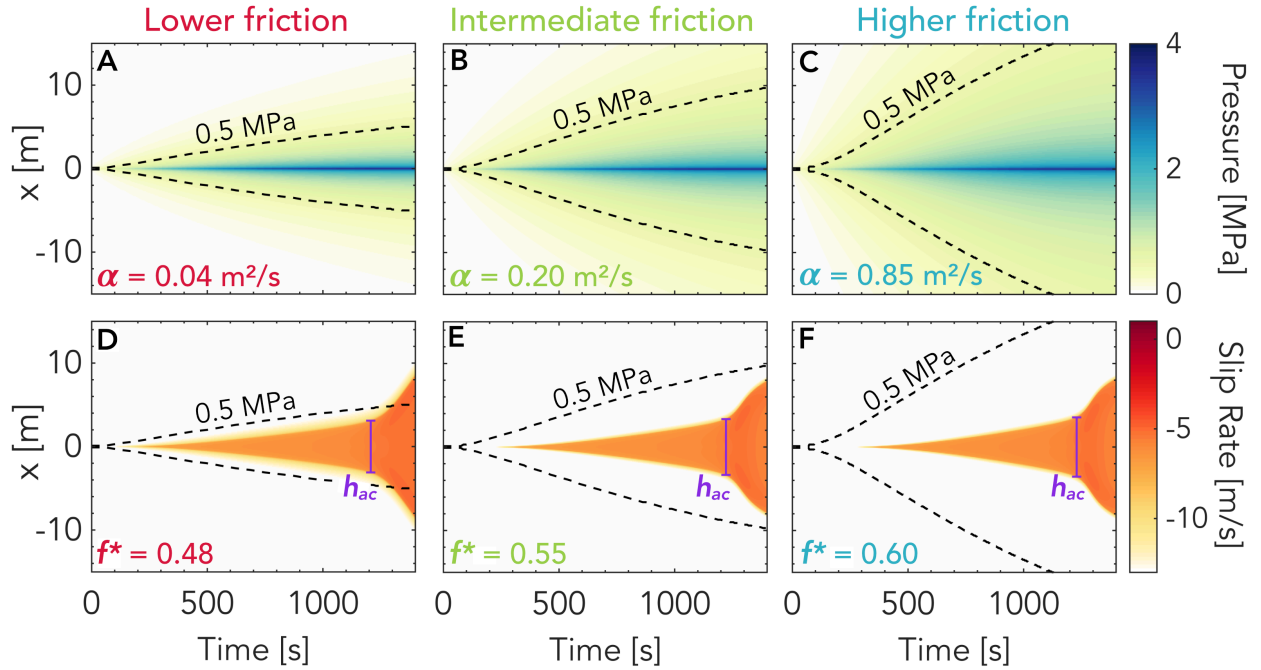

Figure 3. Whether the slipping zone is contained within or outruns the pressurized zone depends on fault friction. Spatial and temporal evolution of (A-C) pore fluid pressure and (D-F) slip rate for the three scenarios of Figure 2 during pressurization. The purple line shows the estimate h_{ac} of the slipping zone for the acceleration stage. Black dashed lines indicate the extent of the pressurized zone defined by 0.5 MPa fluid pressure contours. During the pressurization stage, the slipping zone of the lower-friction case outruns the pressurized zone while the intermediate- and higher-friction cases remain confined to the pressurized zone.

Figure 4. Prolonged injection reveals the diverging stability of the different fault models. Same as Figure 2 (A-B) and Figure 3 (C-E) but for a longer injection scenario, keeping the pressure at the center of the fault constant past 1400 s instead of decreasing it. The low-friction case (red in A, C) produces a runaway earthquake rupture much sooner than the intermediate-friction case (green in A, D), while the higher-friction case (blue in A, E) - which is consistent with most known information about the fault - results in a self-arresting earthquake confined to the pressurized zone (blue).

Acknowledgments

This study was supported by the National Science Foundation (Grants EAR 1151926 and EAR 1724686), the NSF-IUCRC Center for Geomechanics and Mitigation of Geohazards (projects GMG-4.1, GMG-4.2), the National Sciences and Engineering Research Council of Canada (PGSD-3-517078-2018), and the French government through the UCAJEDI Investments in the Future project managed by the National Research Agency (ANR) with the reference number ANR-15-IDEX-01. The computations presented here were conducted on the Caltech High Performance Cluster. The data supporting the analysis and conclusions is given in Figures and Tables, in the main text, and supplementary materials. Model outputs and the experimental data from the Guglielmi et al. 2015 field experiment are accessible through the CaltechDATA repository (<https://data.caltech.edu/records/1891>). We thank Jean-Philippe Avouac, Pathikrit Bhattacharya, Yves Guglielmi, and Robert C. Viesca for helpful discussions as well as Valère Lambert and Oliver Stephenson for help with the simulation code. The authors declare no competing interests. Data from the field experiment as reported in Guglielmi et al. (2015) can be found in the supplementary materials.

Introduction

The following supporting information offers further details on the numerical model and its assumptions as well as derivations of simple formulations and additional figures that illustrate how certain combinations of parameters control the simulation results.

Text S1. Numerical modeling of fluid-induced fault slip

We model fluid injection into a fault zone and subsequent fault slip using a fully-dynamic 2D boundary integral method capable of simulating the complete seismic cycle including both aseismic and seismic deformation. The model is based on an antiplane (Mode III) formulation in which the fault slips solely along the dip direction and variables vary along strike only. Fault slip is governed by the following elastodynamic equation (Lapusta et al., 2000):

$$\tau(x, t) = \tau_{ini} + F(\delta(x, t)) - \frac{\mu}{2c_s} V(x, t) \quad (S1)$$

where τ is the shear stress, τ_{ini} is the initial shear stress, F is a linear functional which depends on the slip history, $\delta(x, t)$, μ is the shear modulus of the elastic medium, c_s is the shear wave speed, and V is the slip rate.

The fault is governed by rate-and-state friction, an empirical friction law based on laboratory experiments. It describes the dependence of the coefficient of friction f on the slip rate V and a state variable θ :

$$f(V(x, t), \theta(x, t)) = \left[f^* + a \ln \frac{V(x, t)}{V^*} + b \ln \frac{V^* \theta(x, t)}{D_{RS}} \right] \quad (S2)$$

where a and b are the direct and evolutionary rate-and-state parameters and D_{RS} is the critical slip distance. f^* is the reference coefficient of friction at the reference slip rate V^* . The reference values are usually set arbitrarily but here, by choosing V^* to be on the order of the slip rate observed during the accelerated aseismic transient in the field experiment, we attach the following additional meaning to the value of f^* : it is approximately equal to the residual friction reached at the latest stage of the field experiment.

The state variable is assumed to evolve according to the aging law:

$$\frac{\partial \theta(x, t)}{\partial t} = 1 - \frac{V(x, t) \theta(x, t)}{D_{RS}} \quad (S3)$$

We prescribe the fluid pressure at the center of the fault (blue line in Figure 2A, top) similar to the one induced in the field experiment (black dots in Figure 2A, top) to

simulate the fluid injection and let the pressure diffuse axisymmetrically in the fault plane as follows:

$$\frac{\partial p(r, t)}{\partial t} = \alpha \left(\frac{\partial^2 p(r, t)}{\partial r^2} + \frac{1}{r} \frac{\partial p(r, t)}{\partial r} \right) \quad (S4)$$

where $r = |x|$ and α hydraulic diffusivity. The diffusion is numerically implemented using a forward finite difference scheme. We approximate the experimental injection pressure with a smooth parabolic function for the increasing portion of the injection and a linear fit for the decreasing portion. A condition of zero pressure is assumed at the ends of the simulated fault since the fault is dry prior to the injection. The choice of this boundary condition is not essential here because the fault length is larger than the pressure diffusion length in our simulations and simulations with longer faults produce nearly identical results.

As the fault in the experiment is inactive prior to the fluid stimulation, the modeled fault is not loaded tectonically. Fault slip is thus purely fluid-induced, i.e., no significant slip would occur without the injection within the time scales considered in the simulations. We prescribe initial conditions that are consistent with a dormant fault by starting with a highly healed fault (i.e., high initial value of the state variable θ_{ini}). This choice of initial conditions is justified by the long-term simulations without tectonic or fluid pressure loading shown in Figures S1 to S4. The initial values affect some initial behavior/slip of the fault but, long-term, the fault heals under the near-constant values of shear stress, with a power-law decrease in slip rate as well as an increase in state variable over time; at long times, the value of the state variable is approximately equal to the healing time of the fault. This behavior can be predicted analytically: When the fault is well below steady-state ($V\theta/D_{RS} \ll 1$), $\dot{\theta} \sim 1$ and thus $\theta \sim t$. Moreover, with shear stress being almost constant, the rate-and-state friction coefficient is fixed and $\dot{f} = a\dot{V}/V + b/t = 0$, implying that $V \propto t^{-b/a}$. The initial conditions in the intermediate- and high-friction cases in this study are consistent with this behavior. In the low-friction case, although we do prescribe a high initial state variable and a low initial slip rate, the fault needs to be initially above steady state to match the measured

slip behavior at the injection size and therefore not consistent with the behavior described above.

Finally, we also test the effect of the domain size in Figure S5. Increasing the domain size slightly changes the timing of earthquakes but not the overall behavior.

Text S2. Controlling the timing of slip initiation and acceleration

The slip measured at the injection site of the field experiment displays two distinct slip stages that we aim to reproduce in our simulations. Stage I starts when slip rates attain $\sim 10^{-7}$ m/s and significant slip initiates, at about 400 s. Stage II is characterized by even higher slip velocities of about $\sim 10^{-6}$ m/s, at about ~ 1200 s. Understanding how the different model parameters govern the onsets of Stages I and II is key to arriving at simulations that replicate the observations.

At the beginning of all simulations, slip rates are low and inertial effects are negligible. Eq. S1 and S2 then reduce to:

$$\tau_{ini} = f(x, t)[\sigma - p(x, t)] \quad (S5)$$

As p is increased, the friction coefficient, f , must increase proportionally for Eq. S5 to remain true since τ_{ini} stays constant over time and the contribution of F is negligible because no significant slip has occurred yet. The coefficient of friction continues increasing until slip becomes significant. The onset of significant slip thus approximately coincides with the maximum friction reached during the simulation. This peak friction, f^p , can be approximated as:

$$f^p = f^* + a \ln \frac{V_s}{V^*} + b \ln \frac{V^* \theta_{ini}}{D_{RS}} \quad (S6)$$

where V_s is the threshold for significant slip, here set at $1e-7$ m/s. The state variable is set to its initial value, θ_{ini} , because it cannot evolve significantly due to lack of slip, and its (large) initial value is not affected by additional healing over hundreds of seconds. Moreover, because the shear stress τ remains approximately constant and equal to the initial value until the peak friction is reached and the fluid pressure at the injection site is known at all times, it is possible to relate f^p to the timing of slip initiation. For

example, for slip initiation at $t_s = 300$ s - at which point the injection fluid pressure is 1.42 MPa - the peak friction at the injection site is:

$$f^p = \frac{\tau_{ini}}{[\sigma - p(0, t_s)]} = \frac{2.15}{[4.00 - 1.42]} = 0.83 \quad (S7)$$

It is thus possible to control t_s by computing f^p with Eq. S7 and selecting f^* , a , b , θ_{ini} and D_{RS} such that Eq. S6 is satisfied.

We find that the onset time, t_{ac} , of the slip acceleration starting at ~ 1200 s (i.e., Stage II) coincides with the time at which steady state is reached at the injection site (Dublanche, 2019). This also corresponds to the time at which the coefficient of friction at the injection site reaches its residual value, $f^r \sim f^*$, down from its peak value f^p . The critical slip distance, δ_c , over which this frictional weakening occurs can be approximated as:

$$\delta_c \sim \frac{f^p - f^*}{b/D_{RS}} \quad (S8)$$

since $\frac{\partial f}{\partial \delta} \sim \frac{b}{D_{RS}}$. Furthermore, from elasticity, slip is related to stress drop by:

$$\Delta \delta \propto \frac{\Delta \tau h}{\mu} \quad (S9)$$

where h is the length of the slipping zone. When $\Delta \delta = \delta_c$ at the center of the fault:

$$\frac{\Delta \tau h}{\mu} \propto \frac{f^p - f^*}{b/D_{RS}} \quad (S10)$$

Rearranging Eq. S10, we can find the estimate of the slipping zone size, h_{ac} , at which steady state is reached and Stage II is initiated:

$$h_{ac} \propto \frac{\mu D_{RS}}{b} \frac{f^p - f^*}{\Delta \tau} \quad (S11)$$

Eq. S11 can be rewritten in terms of known parameters as:

$$h_{ac} \propto \frac{\mu D_{RS}}{b} \frac{a \ln \frac{V_s}{V^*} + b \ln \frac{V^* \theta_{ini}}{D_{RS}}}{\tau_{ini} - f^* [\sigma - p(0, t_{ac})]} \quad (S12)$$

For all the simulations presented in this work, we find that

$$h_{ac} = 3 \frac{\mu D_{RS}}{b} \frac{a \ln \frac{V_s}{V^*} + b \ln \frac{V^* \theta_{ini}}{D_{RS}}}{\tau_{ini} - f^*[\sigma - p(0, t_{ac})]} \quad (S13)$$

provides a good estimate of the slipping zone length at which the slip transitions to Stage II. Note that if $(\sigma - p)$ remained constant throughout the simulation, Eq. S11 would reduce to $h_{ac} \propto \mu D_{RS}/b$ which is similar to the condition for acceleration $k < k_b$ (where k is stiffness) in the spring-block slider model (Dieterich, 1992; Helmstetter & Shaw, 2009) and to the condition $h > L_b$ for acceleration on continuum fault segments that are far above steady-state (Rubin & Ampuero, 2005). Eq. S11 is also similar to the findings for seismic slip nucleation in slip-weakening friction models (Uenishi & Rice, 2003; Viesca & Rice, 2012) except that h_{ac} depends on pressure; specifically on the maximum value of pressure (at the injection site). The fact that this lengthscale does not depend - at least to first order - on the extent or shape of the pore pressure distribution is also consistent with prior findings (Uenishi & Rice, 2003; Viesca & Rice, 2012). At the same time, h_{ac} is different from some of the discussed critical lengthscales, since it does not signify the transition to dynamic, inertially-controlled earthquake slip, but rather corresponds to the beginning of the different quasi-static slip stage in this particular experiment. The existence of h_{ac} is linked to the two-stage quasi-static slip process in the field experiment which the simulations are trying to emulate. The associated evolution of the friction coefficient - with sharp increase to a peak value, then near-linear decrease vs. slip with the slope of b , and then near-constant value - is likely related to the relatively rapid increase of the pore pressure at the injection site compared to the timescale of state variable evolution considered in this work.

To demonstrate that Eq. S13 holds, in Figures S12(A-C) and S13 we show 3 simulations in which h_{ac} is increased compared to the intermediate-friction case by increasing μ (pink), increasing D_{RS} (yellow) or decreasing b (turquoise) while keeping t_s constant. Figures S12(D-E) and S14 show simulations in which both t_s and h_{ac} are increased by increasing f^* (pink) or θ_{ini} (yellow). Figures S12(F) and S14 also show a case (turquoise) in which both t_s and h_{ac} are kept the same as in the intermediate-friction

reference case but t_{ac} is delayed due to the decreased hydraulic diffusivity α which controls how fast the slipping zone expands during Stage I. In all cases, the onset of Stage II is delayed compared to the intermediate-friction reference case. Thus, parameters μ , D_{RS} , b , t_s and α have a primary control on the onset of Stage II observed in all simulations shown in this work.

As for the amplitude and slope of the slip acceleration, four parameters - f^* , a , μ and α - have been identified to play a key role in controlling them as shown in Figures S15 to S19.

Table S1. Model parameters for the three cases presented in Figures 2-4 in the main text.

Properties	Symbol	Low Friction	Intermediate Friction	High Friction
Total fault length [m]	x_{tot}	250	250	250
Frictional interface length [m]	x_{fr}	200	200	200
Initial shear stress [MPa]	τ_{ini}	2.15	2.15	2.15
Initial normal stress [MPa]	σ_{ini}	4.00	4.00	4.00
Initial coefficient of friction	f_{ini}	0.5375	0.5375	0.5375
Reference coefficient of friction	f^*	0.4815	0.5500	0.6000
Reference slip rate [m/s]	V^*	10^{-6}	10^{-6}	10^{-6}
Direct effect frictional parameter	a	0.01500	0.01125	0.01125
Evolutionary effect frictional parameter	b	0.01600	0.01600	0.01600
Critical slip distance [μm]	D_{RS}	16.75	16.75	16.75
Hydraulic diffusivity [m^2/s]	α	0.04	0.20	0.85
Initial state variable [s]	θ_{ini}	1.21e12	2.38e12	7.00e12
Shear modulus [GPa]	μ	10	10	10

Figure S1. Simulations that illustrate long-term fault healing in the absence of slip, with $f^* = 0.550$, $f_{ini} = 0.525$, $a = 0.011$, and $b = 0.016$, varying the initial closeness to steady state ($\Omega_{ini} = V_{ini}\theta_{ini}/D_{RS}$). No matter what the initial values are, all cases eventually undergo a logarithmic decrease in slip rate and an increase in state variable with time. Note that the time axis is logarithmic. The thick dashed lines indicate the slopes discussed in the Text S1.

Figure S2. Simulations that illustrate long-term fault healing in the absence of slip, with $f^* = 0.550$, $f_{ini} = 0.575$, $a = 0.011$, and $b = 0.016$, varying the initial closeness to steady state ($\Omega_{ini} = V_{ini}\theta_{ini}/D_{RS}$). No matter what the initial values are, all cases eventually undergo a logarithmic decrease in slip rate and an increase in state variable with time, even the initially above steady-state case which experiences a run-away earthquake a few minutes into the simulation. Note that the time axis is logarithmic. The thick dashed lines indicate the slopes discussed in Text S1.

Figure S3. Simulations that illustrate long-term fault healing in the absence of slip, with $f^* = 0.550$, $\Omega_{ini} = 1$, $a = 0.011$, and $b = 0.016$, varying the initial friction coefficient, f_{ini} . No matter what the initial values are, all cases eventually undergo a logarithmic decrease in slip rate and an increase in state variable with time. Note that the time axis is logarithmic. The thick dashed lines indicate the slopes discussed in Text S1.

Figure S4. Simulations that illustrate long-term fault healing in the absence of slip, with $f^* = 0.550$, $a = 0.015$, and $b = 0.016$, varying the initial closeness to steady state ($\Omega_{ini} = V_{ini}\theta_{ini}/D_{RS}$) and initial friction coefficient f_{ini} . No matter what the initial values are, all cases eventually undergo a logarithmic decrease in slip rate and an increase in state variable with time, even the initially above steady-state case which experiences a run-away earthquake a few minutes into the simulation. Note that the time axis is logarithmic. The thick dashed lines indicate the slopes discussed in Text S1.

Figure S5. Prolonged injection simulations with domain sizes of 250 m (solid lines) and 300 m (dashed lines). Changing the domain size slightly changes the timing but not the overall behavior.

Figure S6. Simulated temporal evolution of several quantities at the injection site for the cases of Figure 2A in the main text. From top to bottom: the normalized effective normal stress, slip, normalized slip rate ($V_{dyn} = 10^{-2}$ m/s), state variable, friction coefficient, normalized shear stress and closeness to steady state at the injection site. Note that no earthquakes occur in these simulations as opposed to cases in which the pressure is kept constant at the injection site (Figure 4 in the main text).

Figure S7. Same as Figure 3 in the main text but including the depressurization stage.

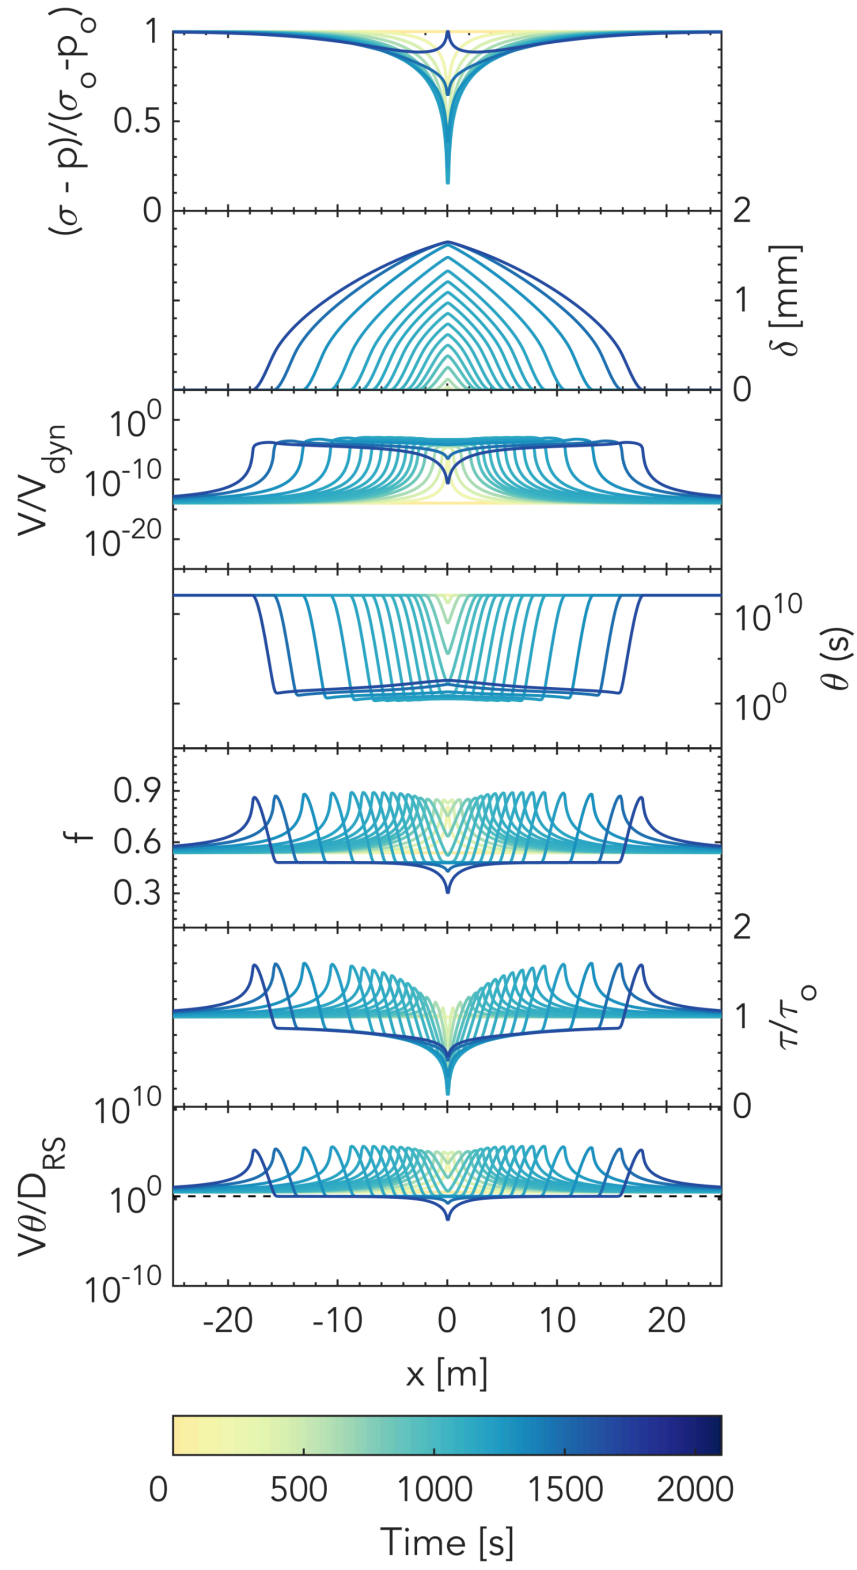

Figure S8. Spatial and temporal evolution of the same quantities as in Fig. S6 for the low-friction case (plotted every 2000 time steps).

Figure S9. Spatial and temporal evolution of the same quantities as in Fig. S6 for the intermediate-friction case (plotted every 6000 time steps).

Figure S10. Spatial and temporal evolution of the same quantities as in Fig. S6 for the high-friction case (plotted every 20000 time steps).

Figure S11. Same as Figure 4C-E in the main text but up to 2500s to enable direct comparison with Figures S12 and S19.

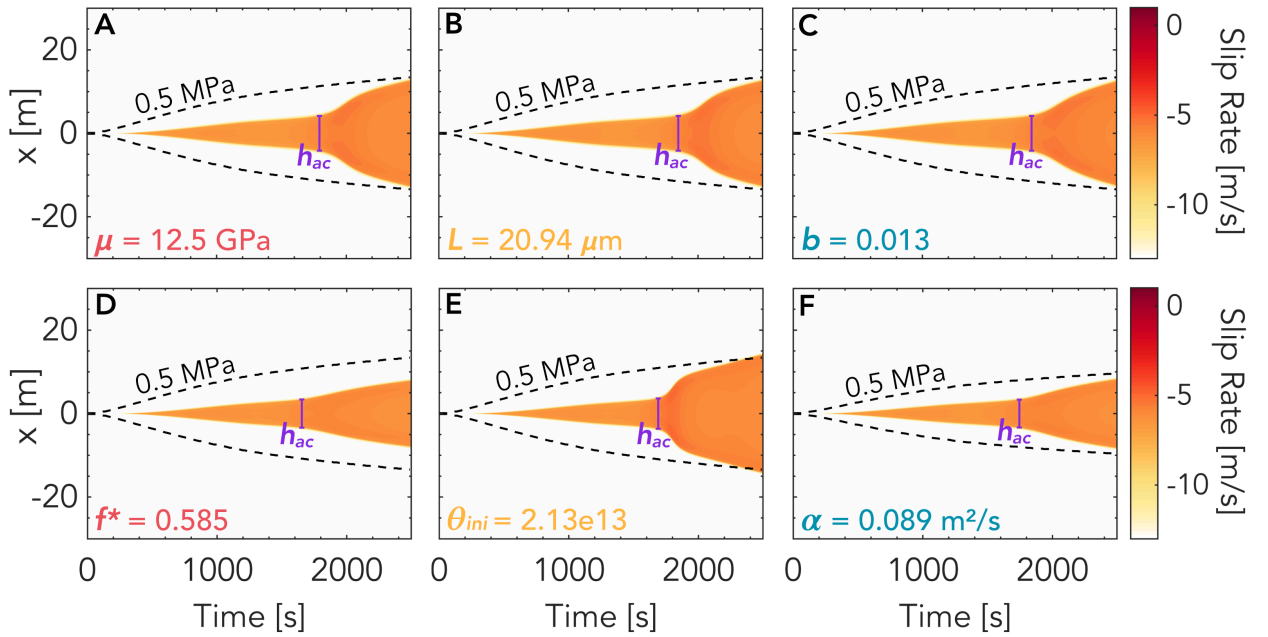

Figure S12. Spatial and temporal evolution of slip rate for prolonged injection (as in Figure S11) but for cases modified from the intermediate-friction case (Figure S11B) in which the onset of Stage II is delayed by (A) increasing μ , (B) increasing D_{RS} , (C) decreasing b , (D) increasing f^* , (E) increasing θ_{ini} , (F) decreasing hydraulic diffusivity α . Note that h_{ac} provides a good estimate of the extent of the sliding region before the onset of Stage II in all these cases.

Figure S13. Temporal evolution of quantities at the injection site and friction vs. slip for the 3 cases shown in Figure S12(A-C) in which μ is increased (pink) or D_{RS} is increased (yellow) or b is decreased (turquoise) compared to the intermediate-friction reference case (green). Note the delay in the transient acceleration compared to the reference case.

Figure S14. Temporal evolution of quantities at the injection site and friction vs slip for the 3 cases shown in Figure S12(D-F) in which f^* is increased (pink) or θ_{ini} is increased (yellow) or α is decreased (turquoise) compared to the intermediate-friction reference case (green). Note the delay in the transient acceleration compared to the reference case.

Figure S15. Temporal evolution of quantities at the injection site and friction vs slip of 2 cases showing the effect of varying f^* while keeping f^p constant. Increasing f^* reduces the amplitude and slope of the transient acceleration.

Figure S16. Temporal evolution of quantities at the injection site and friction vs slip of 2 cases showing the effect of varying a . Increasing a reduces the amplitude and slope of the transient acceleration.

Figure S17. Temporal evolution of quantities at the injection site and friction vs slip of 2 cases showing the effect of varying μ while keeping h_{ac} and f^p constant. Increasing μ reduces the amplitude and slope of the transient acceleration.

Figure S18. Temporal evolution of quantities at the injection site and friction vs slip of 2 cases showing the effect of varying α while keeping t_{ac} and f^p constant. Increasing α increases the amplitude and slope of the transient acceleration.

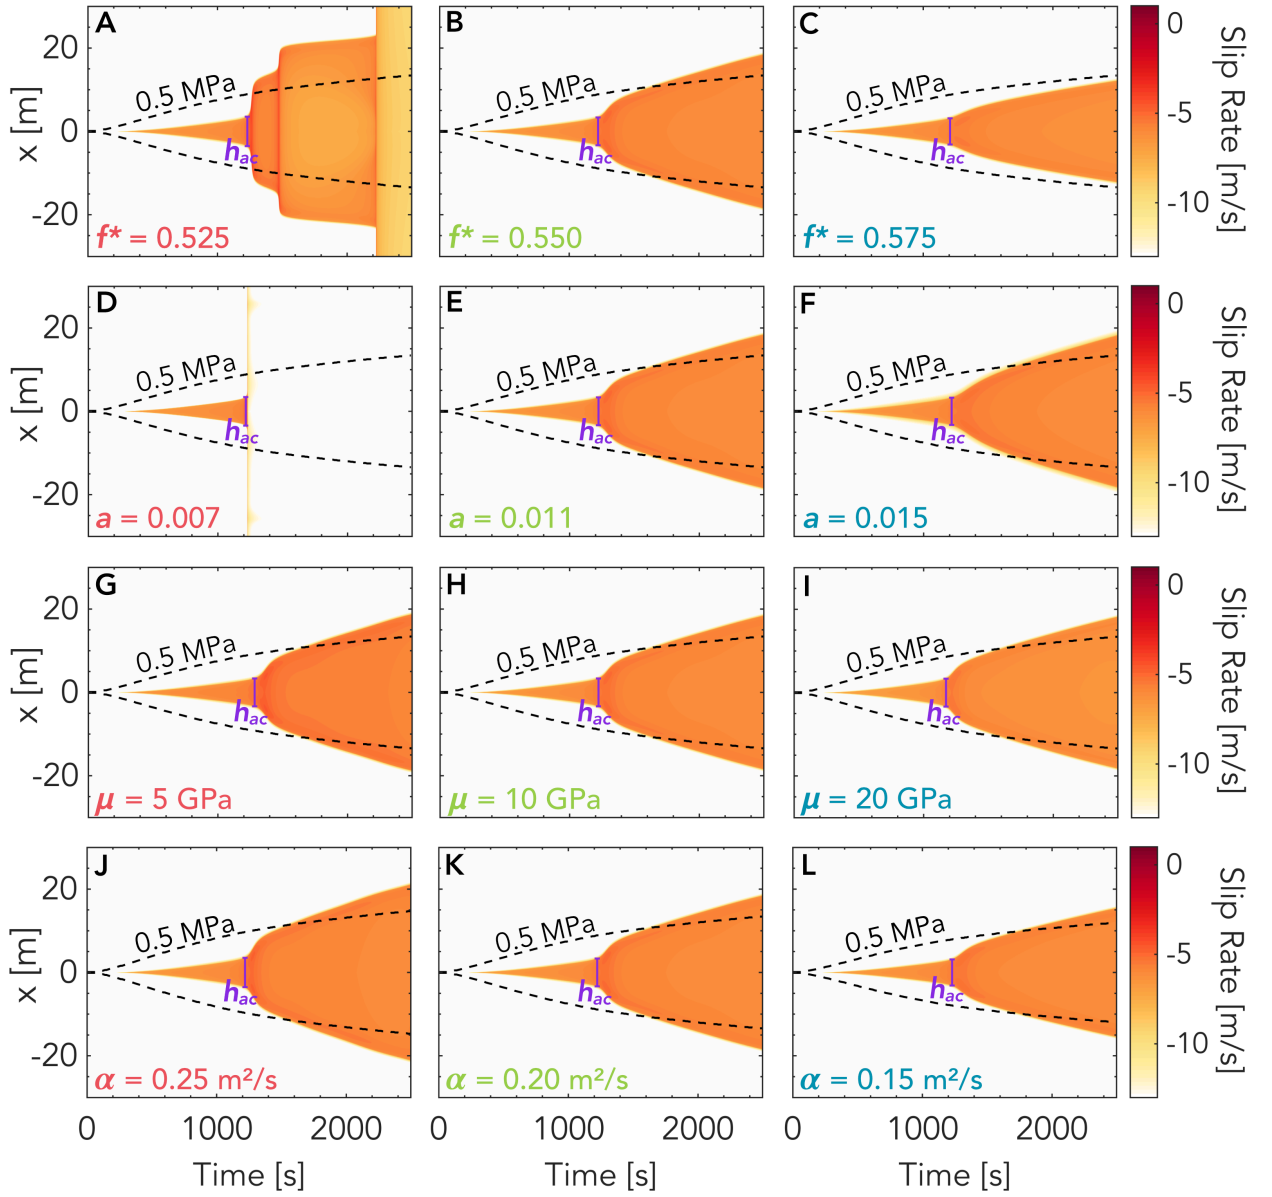

Figure S19. Spatial and temporal evolution of rate for the cases shown in Figures S15 – S18 in which the slope and/or amplitude of the transient acceleration is altered by varying (A,C) f^* , (D,F) a , (G,I) μ and (J,L) α . Panels B, E, H and K all show the reference intermediate-friction case for comparison purposes.

Figure S20. Simulated temporal evolution of several quantities at the injection site for the cases of Figure 4A in the main text. From top to bottom: the normalized effective normal stress, slip, normalized slip rate ($V_{\text{dyn}} = 10^{-2}$ m/s), state variable, friction coefficient, normalized shear stress and closeness to steady state at the injection site.

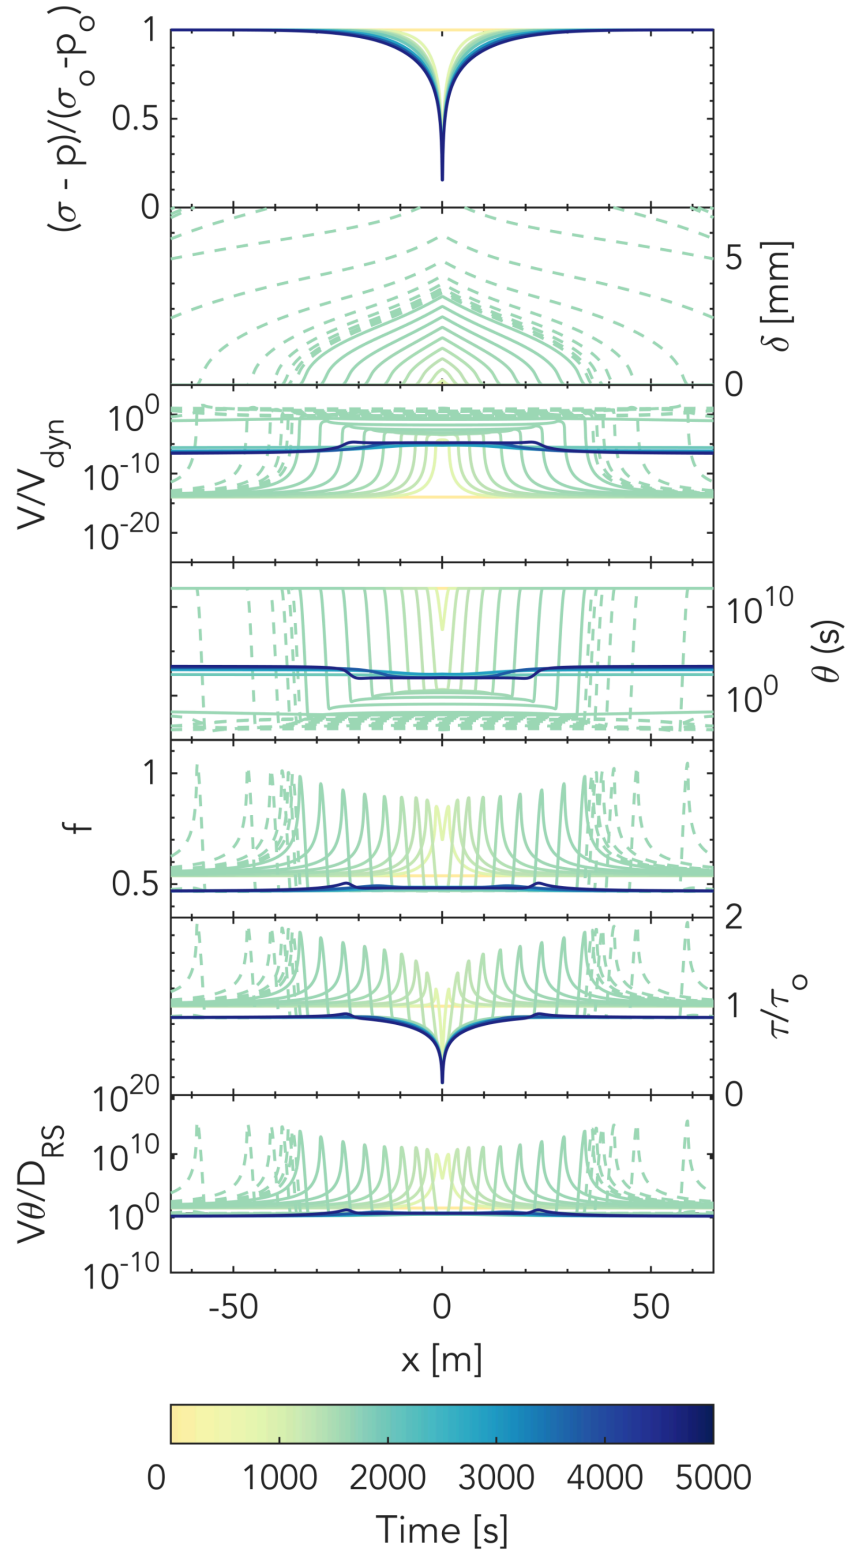

Figure S21. Spatial and temporal evolution of the same quantities as in Fig. S6 for the low-friction prolonged injection case (plotted every 7000 time steps for $V < V_{dyn}$ and every 2000 time steps for $V > V_{dyn}$).

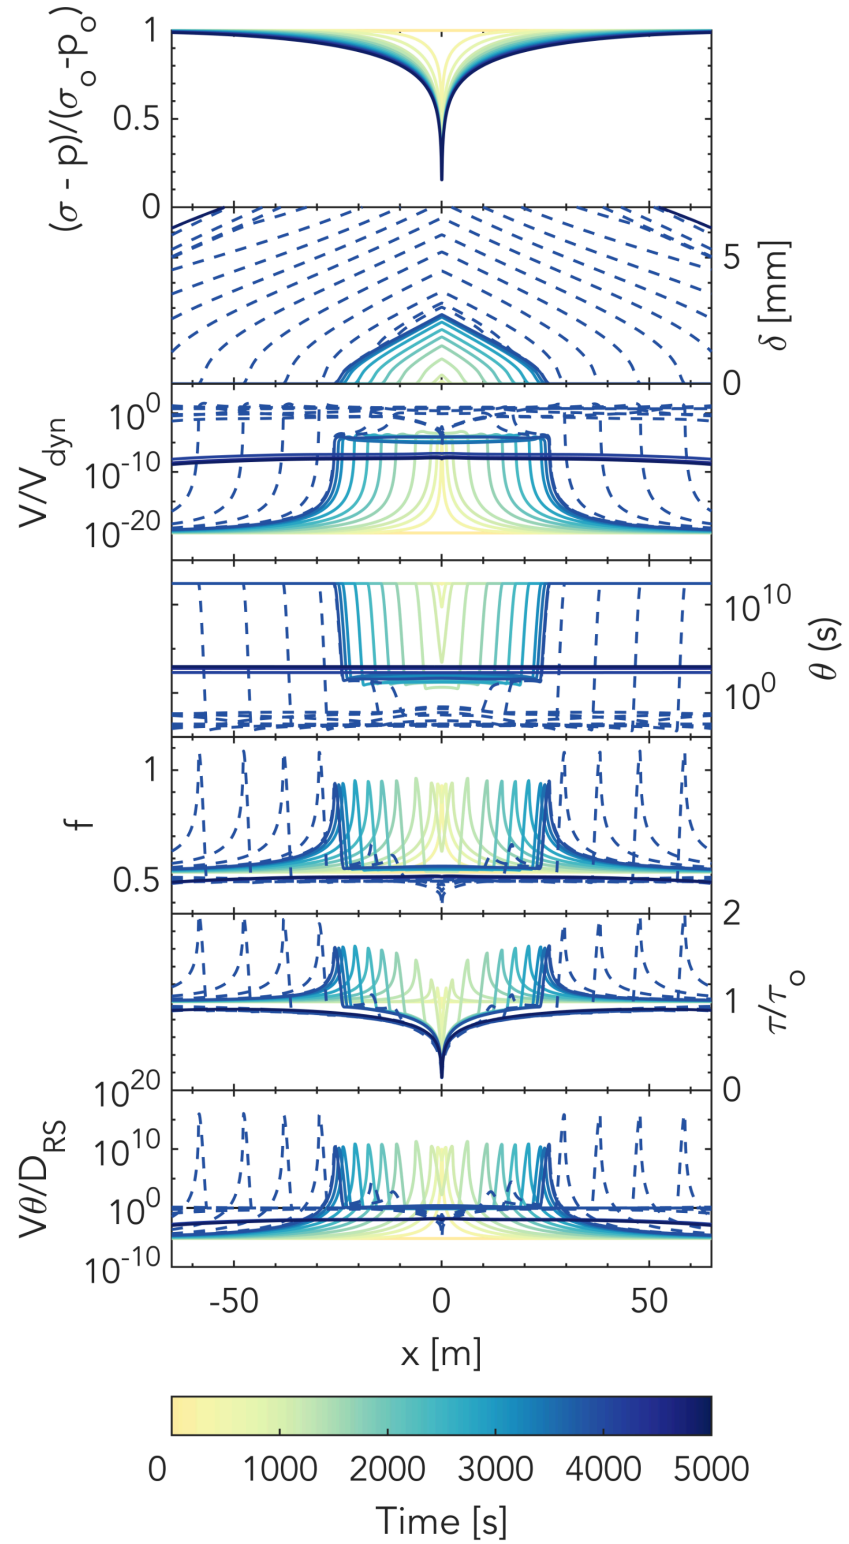

Figure S22. Spatial and temporal evolution of the same quantities as in Fig. S6 for the intermediate-friction prolonged injection case (plotted every 15000 time steps for $V < V_{dyn}$ and every 1000 time steps for $V > V_{dyn}$).

Figure S23. Spatial and temporal evolution of the same quantities as in Fig. S6 for the high-friction prolonged injection case (plotted every 35000 time steps for $V < V_{dyn}$ and every 750 time steps for $V > V_{dyn}$).

Figure S24. Effect of varying pressurization rate on the intermediate-friction case. The timing of events is altered but not the overall behavior, i.e., all simulations still show a transient acceleration followed by a run-away dynamic event.

Figure S25. Effect of varying depressurization rate on a case similar to the low-friction case but with an even lower f^* of 0.46. In this case, the depressurization applied as in Figure 2 in the main text is not sufficient to prevent earthquake nucleation (blue curve). The other two faster depressurization rates successfully suppress the earthquake (yellow and pink curves).

Constraining Fault Friction and Stability with Fluid-Injection Field Experiments

Text S1 to S2

Table S1

Figures S1 to S29

Introduction

The following supporting information describes long-term simulations justifying our choice of initial conditions as well as further discussion on the lengthscale h_{ac} derived in the main text. We also provide additional figures that illustrate the evolution of all variables in the simulation and how certain combinations of parameters control the simulation results.

Text S1. Long-term simulations without tectonic or fluid pressure loading

In the models presented in this study, we prescribe initial conditions that are consistent with a dormant fault by starting with a highly healed fault (i.e., high initial value of the state variable θ_{ini}). This choice of initial conditions is justified by the long-term simulations without tectonic or fluid pressure loading shown in Figures S4-S7. The initial values affect some initial behavior/slip of the fault but, long-term, the fault heals under the near-constant values of shear stress, with a power-law decrease in slip rate as well as an increase in state variable over time; at long times, the value of the state variable is approximately equal to the healing time of the fault. This behavior can be predicted analytically: When the fault is well below steady-state ($V\theta/D_{RS} \ll 1$), $\dot{\theta} \sim 1$ and thus $\theta \sim t$. Moreover, with shear stress being almost constant, the rate-and-state friction coefficient is fixed and $\dot{f} = a\dot{V}/V + b/t = 0$, implying that $V \propto t^{-b/a}$. The initial conditions in the intermediate- and high-friction cases in this study are consistent with this behavior. In the low-friction case, although we do prescribe a high initial state variable and a low initial slip rate, the fault needs to be initially above steady state to match the measured slip behavior at the injection size and therefore not consistent with the behavior described above.

Text S2. h_{ac} : Estimate of slipping zone length at slip acceleration

In the main text, we derived an estimate of the slipping zone length at the time of slip acceleration (beginning of Stage 3). If $(\sigma - p)$ remained constant throughout the simulation, Eq. (11) would reduce to $h_{ac} \propto \mu D_{RS}/b$ which is similar to the condition for acceleration $k < k_b$ (where k is stiffness) in the spring-block slider model (Dieterich, 1992; Helmstetter & Shaw, 2009) and to the condition $h > L_b$ for acceleration on continuum fault segments that are far above steady-state (Rubin & Ampuero, 2005). Eq. (11) is also similar to the findings for seismic slip nucleation in slip-weakening friction models (Uenishi & Rice, 2003; Viesca & Rice, 2012) except that h_{ac} depends on pressure; specifically on the maximum value of pressure (at the injection site). The fact that this lengthscale does not depend - at least to first order - on the extent or shape of

the pore pressure distribution is also consistent with prior findings (Uenishi & Rice, 2003; Viesca & Rice, 2012). At the same time, h_{ac} is different from some of the discussed critical lengthscales, since it does not signify the transition to dynamic, inertially-controlled earthquake slip, but rather corresponds to the beginning of the different quasi-static slip stage in this particular experiment. The existence of h_{ac} is linked to the two-stage quasi-static slip process in the field experiment which the simulations are trying to emulate. The associated evolution of the friction coefficient - with sharp increase to a peak value, then near-linear decrease vs. slip with the slope of b , and then near-constant value - is likely related to the relatively rapid increase of the pore pressure at the injection site compared to the timescale of state variable evolution considered in this work.

To demonstrate that Eq. (11) holds, in Figures S12 and S14(A-C) we show 3 simulations in which h_{ac} is increased compared to the intermediate-friction case by increasing μ (pink), increasing D_{RS} (yellow) or decreasing b (turquoise) while keeping t_s constant. Figures S13 and S14(D-E) show simulations in which both t_s and h_{ac} are increased by increasing f^* (pink) or θ_{ini} (yellow). Figures S13 and S14(F) also show a case (turquoise) in which both t_s and h_{ac} are kept the same as in the intermediate-friction reference case but t_{ac} is delayed due to the decreased hydraulic diffusivity α which controls how fast the slipping zone expands during Stage 2. In all cases, the onset of Stage 3 is delayed compared to the intermediate-friction reference case. Thus, parameters μ , D_{RS} , b , t_s and α have a primary control on the onset of Stage 3 observed in all simulations shown in this work.

As for the amplitude and slope of the slip acceleration, four parameters - f^* , a - b , μ and α - have been identified to play a key role in controlling them as shown in Figures S15 to S19.

Table S1. Model parameters for the three cases presented in Figures 2-4 in the main text.

Properties	Symbol	Low Friction	Intermediate Friction	High Friction
Total fault length [m]	x_{tot}	250	250	250
Frictional interface length [m]	x_{fr}	200	200	200
Initial shear stress [MPa]	τ_{ini}	2.15	2.15	2.15
Initial normal stress [MPa]	σ_{ini}	4.00	4.00	4.00
Initial coefficient of friction	f_{ini}	0.5375	0.5375	0.5375
Reference coefficient of friction	f^*	0.4815	0.5500	0.6000
Reference slip rate [m/s]	V^*	10^{-6}	10^{-6}	10^{-6}
Direct effect frictional parameter	a	0.01500	0.01125	0.01125
Evolutionary effect frictional parameter	b	0.01600	0.01600	0.01600
Critical slip distance [μm]	D_{RS}	16.75	16.75	16.75
Hydraulic diffusivity [m^2/s]	α	0.04	0.20	0.85
Initial state variable [s]	θ_{ini}	1.21e12	2.38e12	7.00e12
Shear modulus [GPa]	μ	10	10	10

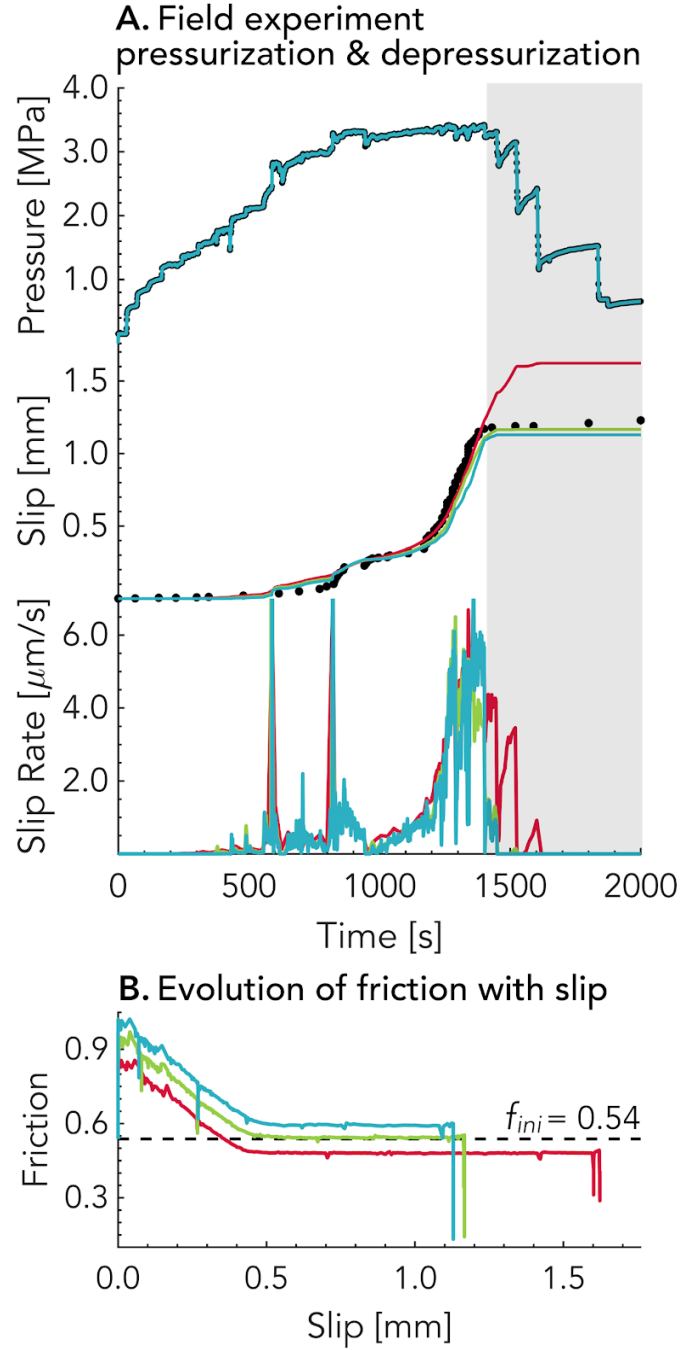

Figure S1. Temporal evolution of pore pressure, slip and slip rate and evolution of friction as a function of slip as in Figure 2AB in the main text but for the exact pressure history. The simulated slip rate is similar but noisier and harder to interpret.

Figure S2. Spatial and temporal evolution of pore pressure and slip as Figure 3 in the main text but for the exact pressure history as in Figure S1 and including the depressurization stage.

Figure S3. Temporal evolution of several quantities at the injection site for the prolonged injection simulations (Figure 4) with domain sizes of 250 m (solid lines) and 300 m (dashed lines). From top to bottom: the normalized effective normal stress, slip, normalized slip rate ($V_{dyn} = 10^{-2}$ m/s), state variable, friction coefficient, normalized shear stress and closeness to steady state at the injection site. Changing the domain size slightly changes the timing of the dynamic events but not the overall behavior.

Figure S4. Simulations that illustrate long-term fault healing in the absence of slip, with $f^* = 0.550$, $f_{ini} = 0.525$, $a = 0.011$, and $b = 0.016$, varying the initial closeness to steady state ($\Omega_{ini} = V_{ini}\theta_{ini}/D_{RS}$). No matter what the initial values are, all cases eventually undergo a logarithmic decrease in slip rate and an increase in state variable with time. Note that the time axis is logarithmic. The thick dashed lines indicate the slopes discussed in the Text S1.

Figure S5. Simulations that illustrate long-term fault healing in the absence of slip, with $f^* = 0.550$, $f_{ini} = 0.575$, $a = 0.011$, and $b = 0.016$, varying the initial closeness to steady state ($\Omega_{ini} = V_{ini}\theta_{ini}/D_{RS}$). No matter what the initial values are, all cases eventually undergo a logarithmic decrease in slip rate and an increase in state variable with time, even the initially above steady-state case which experiences a run-away earthquake a few minutes into the simulation. Note that the time axis is logarithmic. The thick dashed lines indicate the slopes discussed in Text S1.

Figure S6. Simulations that illustrate long-term fault healing in the absence of slip, with $f^* = 0.550$, $\Omega_{ini} = 1$, $a = 0.011$, and $b = 0.016$, varying the initial friction coefficient, f_{ini} . No matter what the initial values are, all cases eventually undergo a logarithmic decrease in slip rate and an increase in state variable with time. Note that the time axis is logarithmic. The thick dashed lines indicate the slopes discussed in Text S1.

Figure S7. Simulations that illustrate long-term fault healing in the absence of slip, with $f^* = 0.550$, $a = 0.015$, and $b = 0.016$, varying the initial closeness to steady state ($\Omega_{\text{ini}} = V_{\text{ini}}\theta_{\text{ini}}/D_{\text{RS}}$) and initial friction coefficient f_{ini} . No matter what the initial values are, all cases eventually undergo a logarithmic decrease in slip rate and an increase in state variable with time, even the initially above steady-state case which experiences a run-away earthquake a few minutes into the simulation. Note that the time axis is logarithmic. The thick dashed lines indicate the slopes discussed in Text S1.

Figure S8. Simulated temporal evolution of several quantities at the injection site for the cases of Figure 2A in the main text. From top to bottom: the normalized effective normal stress, slip, normalized slip rate ($V_{dyn} = 10^{-2}$ m/s), state variable, friction coefficient, normalized shear stress and closeness to steady state at the injection site. Note that no earthquakes occur in these simulations as opposed to cases in which the pressure is kept constant at the injection site (Figure 4 in the main text).

Figure S9. Spatial and temporal evolution of the same quantities as in Fig. S8 for the low-friction case (plotted every 2000 time steps).

Figure S10. Spatial and temporal evolution of the same quantities as in Fig. S8 for the intermediate-friction case (plotted every 6000 time steps).

Figure S11. Spatial and temporal evolution of the same quantities as in Fig. S8 for the high-friction case (plotted every 20000 time steps).

Figure S12. Temporal evolution of quantities at the injection site and friction vs. slip for prolonged injection but for cases in which the onset of Stage 3 is delayed by increasing μ (pink), increasing D_{RS} (yellow) or decreasing b (turquoise) compared to the intermediate-friction reference case (green). Note the delay in the transient acceleration compared to the reference case. Parameter values modified from the intermediate-friction scenario are listed at the top right corner.

Figure S13. Temporal evolution of quantities at the injection site and friction vs. slip for prolonged injection but for cases in which the onset of Stage 3 is delayed by increasing f^* (pink), increasing θ_{ini} (yellow) or decreasing α (turquoise) compared to the intermediate-friction reference case (green). Note the delay in the transient acceleration compared to the reference case. Parameter values modified from the intermediate-friction scenario are listed at the top right corner.

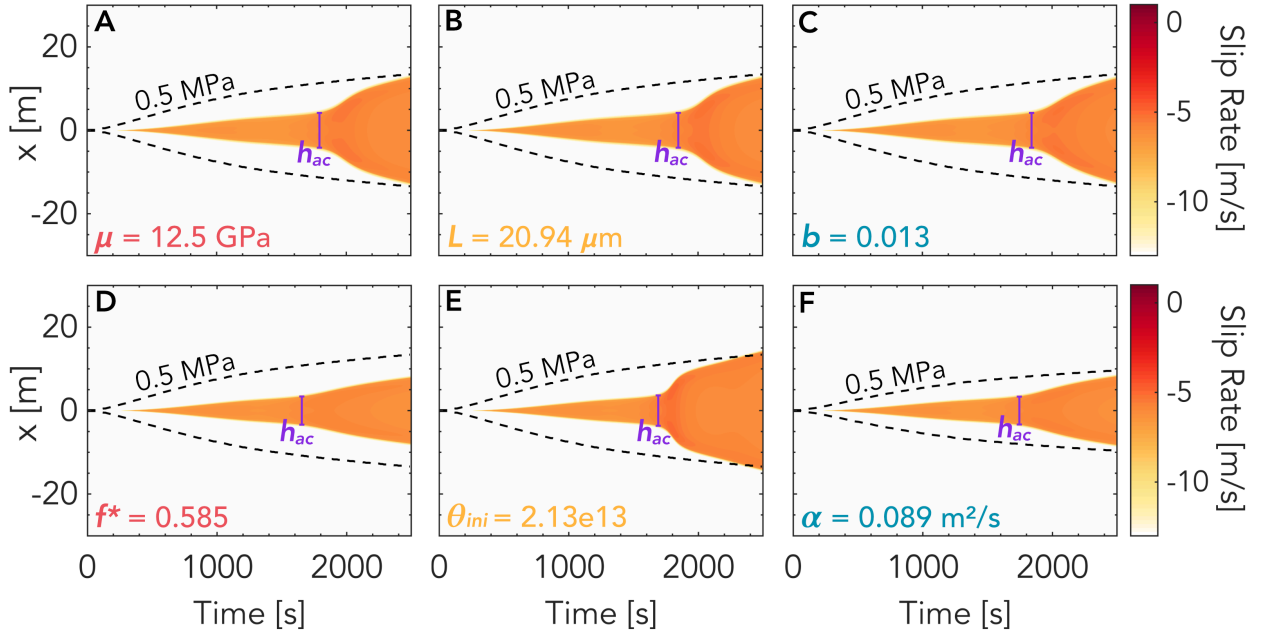

Figure S14. Spatial and temporal evolution of slip rate for the modified prolonged injection cases shown in Figures S12 and S13 in which the onset of Stage 3 is delayed by (A) increasing μ , (B) increasing D_{RS} , (C) decreasing b , (D) increasing f^* , (E) increasing θ_{ini} , (F) decreasing hydraulic diffusivity α . Note that h_{ac} provides a good estimate of the extent of the sliding region before the onset of Stage 3 in all these cases.

Figure S15. Temporal evolution of quantities at the injection site and friction vs slip of 2 cases showing the effect of varying f^* while keeping f^p constant. Increasing f^* reduces the amplitude and slope of the transient acceleration. Parameter values modified from the intermediate-friction scenario are listed at the top right corner.

Figure S16. Temporal evolution of quantities at the injection site and friction vs slip of 2 cases showing the effect of varying a . Increasing a reduces the amplitude and slope of the transient acceleration. Parameter values modified from the intermediate-friction scenario (green) are listed at the top right corner.

Figure S17. Temporal evolution of quantities at the injection site and friction vs slip of 2 cases showing the effect of varying μ while keeping h_{ac} and f^p constant. Increasing μ reduces the amplitude and slope of the transient acceleration. Parameter values modified from the intermediate-friction scenario (green) are listed at the top right corner.

Figure S18. Temporal evolution of quantities at the injection site and friction vs slip of 2 cases showing the effect of varying α while keeping t_{ac} and f^p constant. Increasing α increases the amplitude and slope of the transient acceleration. Parameter values modified from the intermediate-friction scenario (green) are listed at the top right corner.

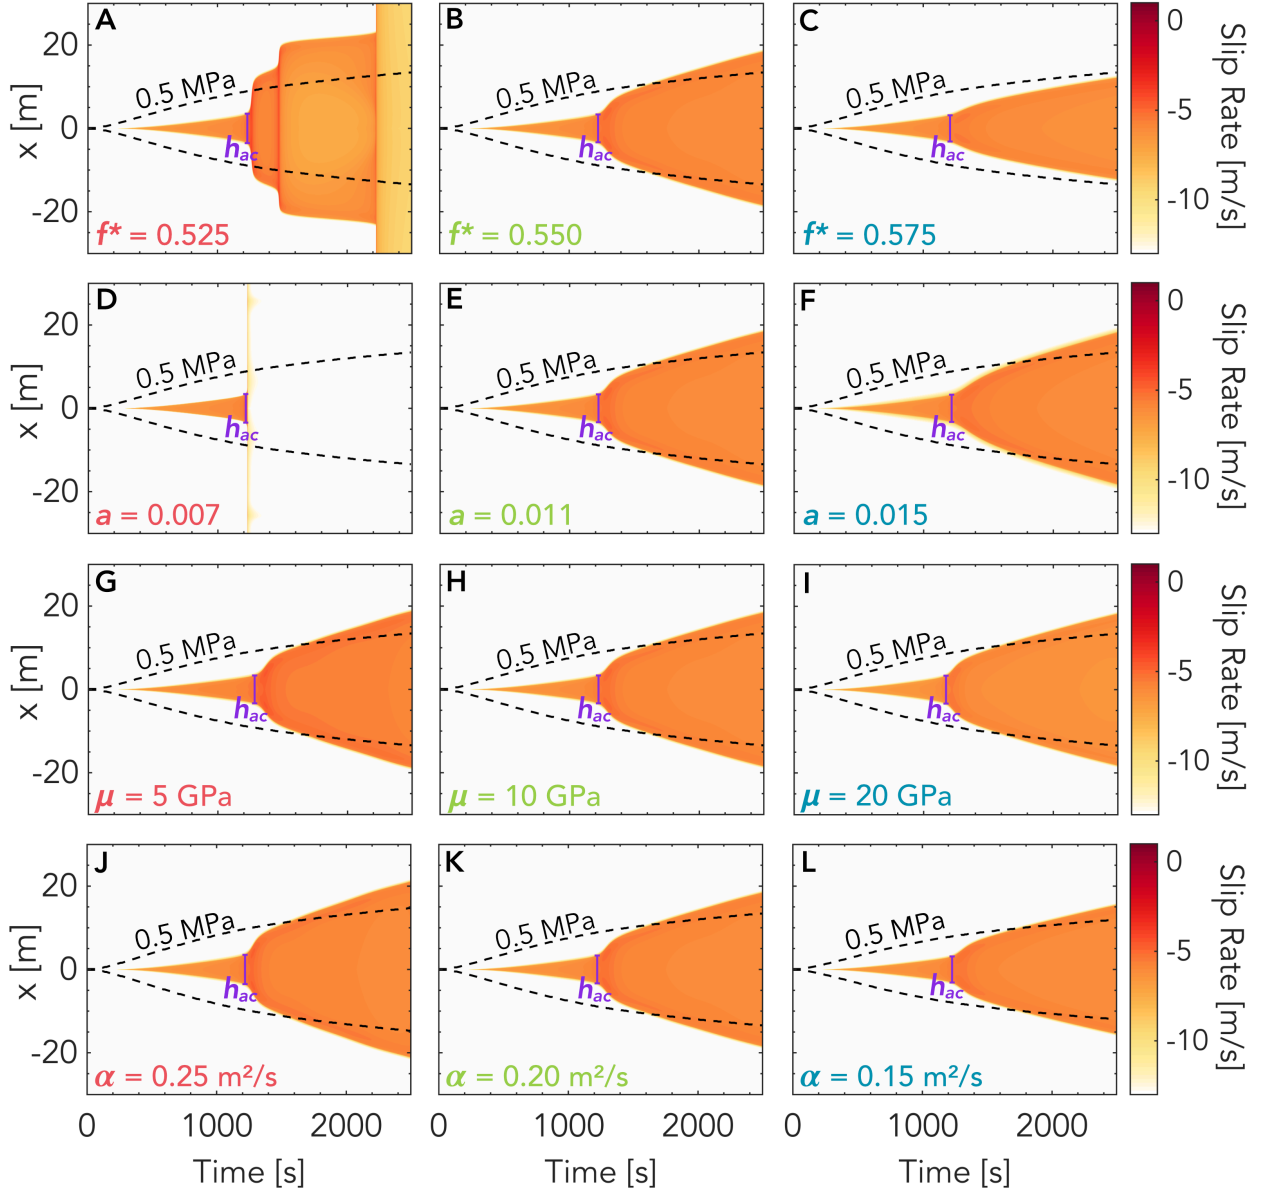

Figure S19. Spatial and temporal evolution of rate for the cases shown in Figures S15 – S18 in which the slope and/or amplitude of the transient acceleration is altered by varying (A,C) f^* , (D,F) a , (G,I) μ and (J,L) α . Panels B, E, H and K all show the reference intermediate-friction case for comparison purposes.

Figures S20. Simulated temporal evolution of several quantities at the injection site varying f^* , keeping all other parameter values as in the intermediate-friction scenario (green).

Figures S21. Simulated temporal evolution of several quantities at the injection site varying α , keeping all other parameter values as in the intermediate-friction scenario (green).

Figure S22. Spatial and temporal evolution of rate for the cases shown in Figures S20. Keeping everything else constant, varying f^* affects the spatial extent of the slipping zone compared to the pressurized zone.

Figure S23. Spatial and temporal evolution of rate for the cases shown in Figures S21. Keeping everything else constant, varying α affects the spatial extent of the slipping zone.

Figure S24: Simulated temporal evolution of several quantities at the injection site for a scenario similar to the low-friction case in the main text but for a slightly rate-strengthening fault with $a = 0.017$, $b = 0.016$, $f^* = 0.475$ and $\theta_{ini} = 1.8e12$ s. Note that in this case an earthquake still nucleates after the injection stopped due to the relatively low residual friction f^r compared to f_{ini} .

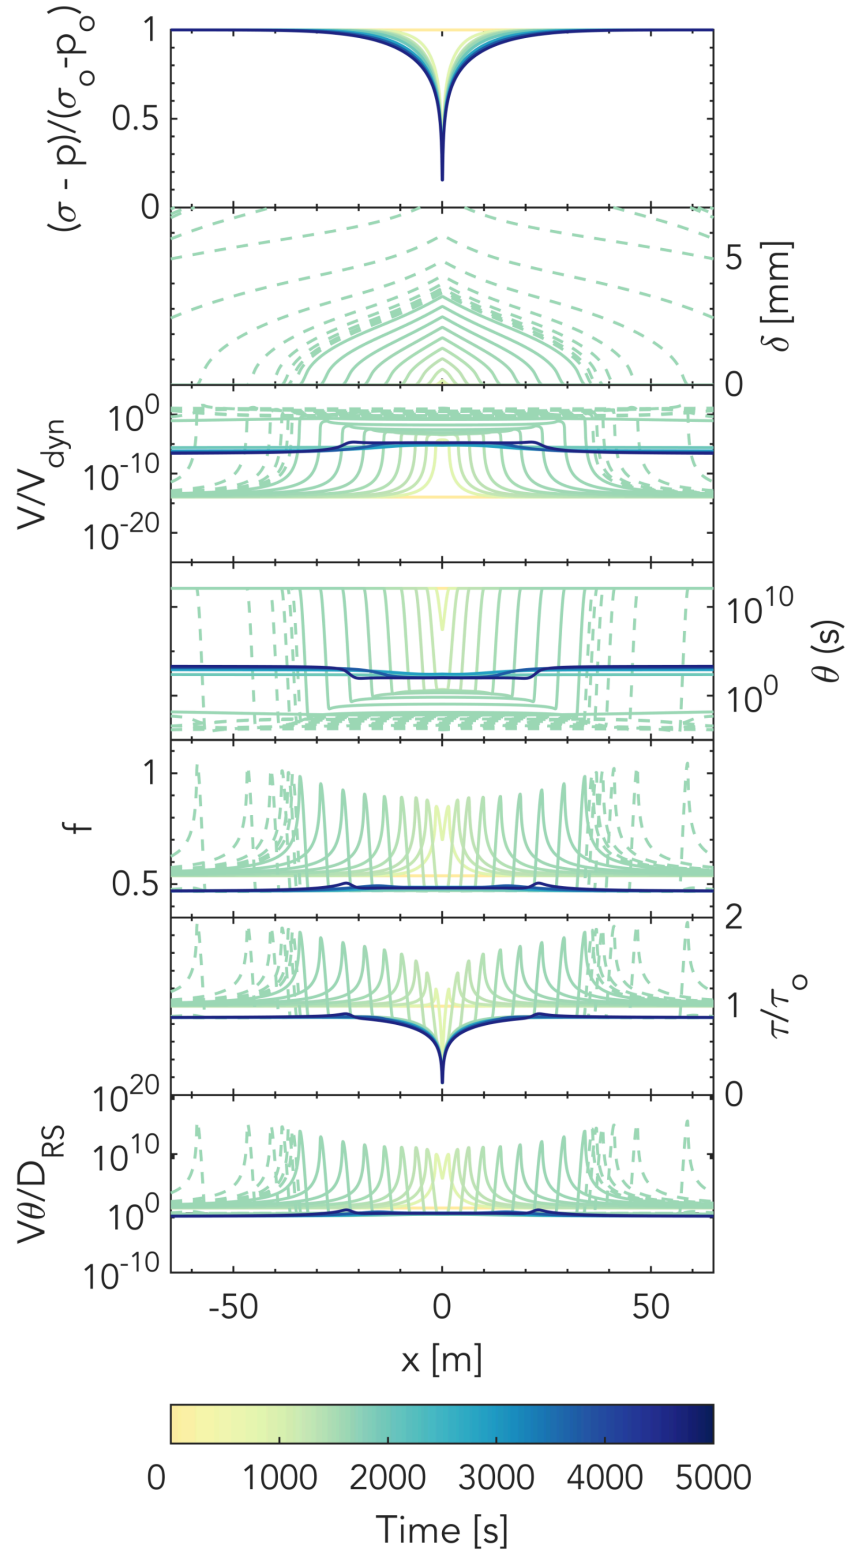

Figure S25. Spatial and temporal evolution for the low-friction prolonged injection case (plotted every 7000 time steps for $V < V_{dyn}$ and every 2000 time steps for $V > V_{dyn}$).

Figure S26. Spatial and temporal evolution for the intermediate-friction prolonged injection case (plotted every 15000 time steps for $V < V_{dyn}$ and every 1000 time steps for $V > V_{dyn}$).

Figure S27. Spatial and temporal evolution for the high-friction prolonged injection case (plotted every 35000 time steps for $V < V_{dyn}$ and every 750 time steps for $V > V_{dyn}$).

Figure S28. Effect of varying pressurization rate on the intermediate-friction case. The timing of events is altered but not the overall behavior, i.e., all simulations still show a transient acceleration followed by a run-away dynamic event.

Figure S29. Effect of varying depressurization rate on a case similar to the low-friction case but with an even lower f^* of 0.46. In this case, the depressurization applied as in Figure 2 in the main text is not sufficient to prevent earthquake nucleation (yellow curve). The other two faster depressurization rates successfully suppress the earthquake (pink and turquoise curves).
