November 30, 2022

#### Abstract

The empirical constitutive modeling framework of Rate- and State-dependent Friction (RSF) is commonly used to describe the time-dependent frictional response of fault gouge to perturbations from steady sliding. In a previous study (Ferdowsi & Rubin, 2020), we found that a granular-physics-based model of a fault shear zone, with time-independent properties at the contact scale, reproduces the phenomenology of laboratory rock and gouge friction experiments in velocity-step and slide-hold protocols. A few slide-hold-slide simulations further suggested that the granular model might outperform current empirical RSF laws in describing laboratory data. Here, we explore the behavior of the same model in slide-hold and slide-hold-slide protocols over a wide range of sliding velocities, hold durations, and system stiffnesses, and provide additional support for this view. We find that, similar to laboratory data, the rate of stress decay during slide-hold simulations is in general agreement with the "Slip law" version of the RSF equations, using parameter values determined independently from velocity step tests. During reslides following long hold times, the model, similar to lab data, produces a nearly constant rate of frictional healing with log hold time, with that rate being in the range of ~0.5 - 1 times the RSF "state evolution" parameter b. We also find that, as in laboratory experiments, the granular layer undergoes log-time compaction during holds. This is consistent with the traditional understanding of state evolution under the Aging law, even though the associated stress decay is similar to that predicted by the Slip and not the Aging law.

#### 12 Abstract

The empirical constitutive modeling framework of Rate- and State-dependent Friction (RSF) 13 is commonly used to describe the time-dependent frictional response of fault gouge to perturbations 14 from steady sliding. In a previous study (Ferdowsi & Rubin, 2020), we found that a granular-15 physics-based model of a fault shear zone, with time-independent properties at the contact scale, 16 reproduces the phenomenology of laboratory rock and gouge friction experiments in velocity-step 17 and slide-hold protocols. A few slide-hold-slide simulations further suggested that the granular 18 model might outperform current empirical RSF laws in describing laboratory data. Here, we explore 19 the behavior of the same model in slide-hold and slide-hold-slide protocols over a wide range of 20 sliding velocities, hold durations, and system stiffnesses, and provide additional support for this 21 view. We find that, similar to laboratory data, the rate of stress decay during slide-hold simulations 22 is in general agreement with the "Slip law" version of the RSF equations, using parameter values 23 determined independently from velocity step tests. During reslides following long hold times, the 24 model, similar to lab data, produces a nearly constant rate of frictional healing with log hold time, 25 with that rate being in the range of  $\sim 0.5 - 1$  times the RSF "state evolution" parameter b. We also 26 find that, as in laboratory experiments, the granular layer undergoes log-time compaction during 27 holds. This is consistent with the traditional understanding of state evolution under the Aging law, 28 even though the associated stress decay is similar to that predicted by the Slip and not the Aging 29 law. 30

#### 31 1 Introduction

The constitutive framework of Rate- and State-dependent Friction is often used for modeling tran-32 sient frictional behavior of rocks and other Earth materials (e.g., sediment, glacial till), and for 33 simulating frictional instabilities relevant to earthquakes, landslides and earthflows (J. H. Dieterich, 34 1992, 1978, 1979; J. H. Dieterich et al., 1981; Ruina, 1983; J. Dieterich, 1994; Marone, 1998; 35 J. H. Dieterich & Kilgore, 1996; Viesca, 2016; Handwerger et al., 2016; McCarthy et al., 2017). A 36 complete prescription of RSF requires an equation for the evolution of the "state variable" defining 37 the "state" of the sliding interface. Existing versions of this equation are largely empirical, differ 38 fundamentally in the extent to which slip or elapsed time is responsible for state evolution, and fail 39 to satisfactorily match the suite of laboratory experiments they were designed to describe. 40

A popular concept has been that in the absence of sliding, state evolution (frictional strength-41 ening, in such cases) is fundamentally a time-dependent process (J. H. Dieterich, 1972). This hy-42 pothesis has received support first from the observed logarithmic-with-time growth of contact area 43 between transparent samples of PMMA (Polymethyl methacrylate), due to plastic deformation of 44 contacting asperities (J. H. Dieterich & Kilgore, 1994), and more recently from the logarithmic-45 with-time increase in acoustic transmissivity across frictional interfaces in rock (Nagata et al., 2012). 46 Log-time frictional strengthening of stationary surfaces has been shown to also result from increased 47 chemical bonding (Li et al., 2011). The log-time increase in both contact area and chemical bonding 48 have been shown to have a sound theoretical basis (Berthoud et al., 1999; Baumberger & Caroli, 49 2006; Liu & Szlufarska, 2012). Such behavior is embodied in the "Aging" (or "Dieterich") equation 50 for state evolution (Ruina, 1983). Despite its theoretical basis, however, the Aging law accurately 51 describes almost no rock or gouge friction data other than the observed increase in "static" fric-52 tion with the logarithm of hold time in laboratory slide-hold-slide experiments (as measured by the 53 friction peak upon resliding). 54

In contrast, a second popular equation for state evolution (the "Slip" or "Ruina" law) has no 55 well-established theoretical justification, but does a remarkably good job describing the results of 56 laboratory velocity-step experiments, as well as the stress decay during the hold portion of slide-57 hold-slide experiments (Ruina, 1983; Nakatani, 2001; Bhattacharya et al., 2015, 2017). The Aging 58 and Slip laws are asymptotically identical for small perturbations from steady-state sliding, but 59 diverge as the sliding deviates further from steady state. Notably, unlike the Aging law, the Slip 60 law predicts no state evolution in the absence of slip. Nonetheless, the Slip law can still generate an 61 increase in frictional strength approximately as log hold time during slide-hold-slide experiments, 62

due to the small amount of slip accompanying the stress decay during holds applied by an elastic testing machine (Ruina, 1983).

The lack of a physics-based theory for transient friction of rock has motivated exploring the 65 physical and chemical origins of rate-state friction in a variety of scientific communities, and has 66 also brought significant attention to the contributions of the quantity (contact area) versus the quality 67 (shear strength) of contact asperities to the state of a frictional interface (Li et al., 2011; Chen 68 & Spiers, 2016; Tian et al., 2017, 2018; Thom et al., 2018). However, future investigations are 69 needed to address the implications of asperity-scale (sometimes single-asperity-scale) observations 70 for the transient frictional behavior at the macroscopic scale. In addition, more work is necessary 71 to determine if any of the single-asperity-scale observations may reproduce or explain the transient 72 frictional behavior of rock and gouge materials in the lab. 73

In a previous study, we used the discrete element method to simulate the transient frictional 74 behavior of a sheared granular gouge layer in a loading configuration that mimicked traditional rock 75 friction experiments (Ferdowsi & Rubin, 2020). We intentionally implemented constant Coulomb 76 friction and no time-dependence of the properties at grain-grain contacts. We then subjected this 77 simulated fault gouge to a series of velocity-stepping protocols. It is noteworthy that most labo-78 ratory rock friction experiments become to some extent granular gouge experiments after a short 79 shearing displacement, as a result of wear products that develop on even initially bare rock sliding 80 surfaces, and that the RSF phenomenology is observed in both those experiments that start with 81 bare rock surfaces and those that start with a synthetic gouge layer (Marone, 1998). We found 82 that the sheared granular model, like the Slip law for state evolution, successfully reproduces the 83 characteristic transient frictional response of rock and gouge observed in laboratory velocity-step 84 tests. Furthermore, in that study we investigated a limited number of slide-hold and slide-hold-slide 85 (SHS) tests, and found that the stress decay during the holds were consistent with the predictions 86 of the Slip law, which itself is largely consistent with the stress decay observed in laboratory slide-87 hold experiments. During the reslides, on the other hand, the simulations deviated from the Slip 88 law prediction, and it did so in a manner that seemed more consistent with laboratory experiments. 89 Together, these results suggested that the granular flow model might do a better job of describing 90 (room temperature, nominally dry) rock and gouge friction experiments than the existing, largely 91 empirical RSF equations. This is surprising. By eliminating time-dependent chemical reactions and 92 plasticity at grain/grain contacts, we are dispensing with what is traditionally considered to be the 93 source of the rate- and state-dependence of rock friction. All the velocity-dependence and transient 94 response of the granular flow model results from momentum transfer between grains, even at our 95 lowest imposed sliding velocities of  $10^{-4}$  m/s. 96

The purpose of the present paper is to further test the granular flow model as a descriptor of 97 rock friction by more thoroughly examining SHS protocols. Most importantly, for comparison to 98 lab data, we explore a wider range of system stiffnesses. All the SHS simulations in Ferdowsi and 99 Rubin (2020) were conducted at the highest stiffness we could achieve, that limit being set by the 100 elastic stiffness of the gouge layer itself. For velocity-step tests this is desirable; a high stiffness 101 ensures that the inelastic sliding velocity is always nearly the load point velocity, which allows 102 one to infer the RSF parameters directly from the transient frictional response without having to 103 account for a varying velocity. However, for slide-hold tests the inelastic velocity during the hold is 104 always different from the (zero) load-point velocity, and this velocity is controlled to a large extent 105 by the system stiffness. Because the amount of slip during the load-point hold has been used to 106 107 help distinguish between the roles of slip and time in frictional healing (Beeler et al., 1994), in this paper we use two additional stiffnesses more appropriate for those laboratory experiments. We also 108 employ a wider range of sliding velocities than in Ferdowsi and Rubin (2020), as low as 2 mm/s. 109 This is closer to but still somewhat high by laboratory standards. We return to these points in Section 110 3 of the manuscript. 111

If, in the face of these more stringent SHS tests, the physics-based granular flow model continues to perform well relative to the the empirical RSF equations, it could help further develop our understanding of the processes underlying rate-state friction. In addition, if by interrogating the model output we are also able to understand the physics underlying the transient response of the model to velocity perturbations, it might allow the development of approximate equations that could
 be used in numerical simulations of fault slip as a substitute for the RSF equations currently in use.
 This provides the motivation, in Section 5, for using the SHS simulations to further explore the pos sibility that the direct velocity-dependence of friction in the granular simulations can be understood
 in terms of the kinetic energy of the gouge particles (Ferdowsi & Rubin, 2020).

We note that even if the granular model is successful in this sense, this does not imply that 121 time-dependent physical and chemical processes at grain contacts are irrelevant. Indeed, numerous 122 experiments have shown that chemical environment affects the transient behavior of frictional inter-123 faces (Frye & Marone, 2002, e.g.). However, at the moment we lack a physical understanding of the 124 source of RSF (in the sense of also matching most lab friction data) in any system, experimental or 125 numerical. If we are able to achieve this understanding for the inert granular system, this could shed 126 light on the origins of similar behavior in quite different systems. For this reason the results of this 127 study could be of interest to researchers in the fields of granular physics and glassy systems, as well 128 as, given the ubiquity of granular material in fault zones, researchers in fault mechanics. 129

This paper is organized as follows: In Section 2, we describe the relevant aspects of rate-130 state friction, including those aspects that have been seen previously in simulations of granular 131 flow. Section 3 describes the computational model, and important dimensionless parameters that 132 can be used to judge how closely our simulations adhere to the laboratory experiments we compare 133 them to. Section 4 comprises the bulk of the paper - results of the slide-hold and slide-hold-slide 134 simulations and their comparison to relevant lab experiments and models of RSF. Finally, Section 5 135 looks at the energetics of the slide-hold simulations, with an eye toward further evaluating the idea 136 that the granular kinetic energy can be used to understand the source of the instantaneous velocity-137 dependence of friction in these simulations. 138

#### **2** Rate- and State-Dependent Friction background

The empirical framework of rate- and state-dependent friction describes the resistance to sliding as a function two variables: The sliding rate, V, and "something else", commonly referred to as the "state variable"  $\theta$ , that describes the "state" of the sliding interface. In its simplest form, RSF consists of two equations. The first of these is the "friction equation" alluded to above:

$$\mu = \mu_* + a\log\frac{V}{V_*} + b\log\frac{\theta}{\theta_*} \,. \tag{1}$$

Here  $\mu_*$  is the nominal steady-state coefficient of friction at the reference velocity  $V_*$  and state  $\theta_*$ . The RSF parameters *a* and *b* control the magnitude of velocity- and state-dependence of the frictional strength. The second equation is the "state evolution law" describing the time evolution of the state variable  $\theta$ . The two commonly used forms are:

Aging Law: 
$$\frac{d\theta}{dt} = 1 - \frac{V\theta}{D_c}$$
 (2)

Slip Law: 
$$\frac{d\theta}{dt} = -\frac{V\theta}{D_c} \ln \frac{V\theta}{D_c}$$
 (3)

where  $D_c$  is a characteristic slip distance (J. H. Dieterich, 1979; Ruina, 1983). Eq. 2 is often referred to as the Aging law, as state can evolve with time in the absence of slip; Eq. 3 is often referred to as the Slip law, as state evolves only with slip ( $\dot{\theta} = 0$  when V = 0). In general, more than one state variable might be required to adequately describe friction as observed in the laboratory (Ruina, 1983; Ikari et al., 2016).

Previous studies have demonstrated that neither the Aging law nor the Slip law adequately describes the full range of laboratory velocity-stepping and slide-hold-slide loading protocols (Beeler et al., 1994; Kato & Tullis, 2001). Velocity-stepping experiments with a sufficiently stiff system

show that following a change in velocity, friction approaches its new steady-state value quasi-152 exponentially over a characteristic slip distance that is independent of both the magnitude and the 153 sign of the velocity step (Ruina, 1983; Marone, 1998; Blanpied et al., 1998; Bhattacharya et al., 154 2015). This observation holds for both bare rock and gouge samples, and it is consistent with the 155 Slip law prediction for state evolution because the Slip law was designed with that transient behavior 156 in mind (Ruina, 1983; Nakatani, 2001). However, the Aging law predicts a strongly asymmetric and 157 magnitude-dependent transient frictional response to velocity step increases and decreases, behavior 158 that is completely inconsistent with laboratory data (Nakatani, 2001). 159

160 The Aging law was introduced primarily to account for the observation that in SHS experiments, beyond a "cut-off time" that is typically of order 1 s, the peak stress upon resliding increases 161 approximately as the logarithm of the hold time (J. H. Dieterich, 1979; J. H. Dieterich & Kilgore, 162 1994; Marone & Saffer, 2015; Carpenter et al., 2016). However, Bhattacharya et al. (2017) rean-163 alyzed the experimental SHS data of Beeler et al. (1994), conducted using two different machine 164 stiffnesses (and hence two different amounts of interfacial slip during the load-point hold, as the 165 loading machine and rock sample elastically unload), and found that the log-time increase in peak 166 stress upon resliding could be fit about as well by the Slip law as by the Aging law. Bhattacharya 167 et al. (2017) further showed that the nearly logarithmic-with-time stress decay during the load-point 168 holds could be well modeled by the Slip law, which predicts relatively little state evolution owing to 169 the small amount of slip. In contrast, this log-time stress decay is completely inconsistent with the 170 Aging law, which predicts too much strengthening (state evolution) during the holds, and a rate of 171 stress decay that approaches zero as hold time increases (for a/b < 1, as was the case in these exper-172 iments). Despite the failure of the Aging law to fit both velocity-step tests and slide-hold tests, most 173 theoretical justifications for the evolution of state presuppose mechanisms of time-dependent heal-174 ing as embodied by the Aging law (e.g., Baumberger et al., 1999). But even the Slip law is unable 175 to model data from both the hold and reslide portions of SHS tests (Bhattacharya et al., 2017). 176

177

#### 2.1 Granular rate- and state-dependent friction

Both the empirical nature and the inadequacies of the existing RSF equations motivated our 178 previous study, in which we modeled the behavior of a granular gouge layer with no time-dependent 179 plasticity or chemistry at the grain contacts (Ferdowsi & Rubin, 2020). We subjected the gouge layer 180 to velocity-step numerical protocols over load-point velocities  $V_{lp}$  from  $10^{-4}$  to 2 m/s and normal 181 stresses  $\sigma_n$  from 1 to 25 MPa. We found that, in agreement with RSF and multiple previous DEM 182 modeling studies, the simulated granular layer shows a "direct velocity effect" (i.e., an immediate 183 change in friction of the same sign as the imposed velocity step), that is then followed by a gradual 184 "state evolution effect" as friction evolves in the opposite sense toward its new steady-state value 185 (Morgan, 2004; Hatano, 2009; Abe et al., 2002). We further found that the magnitudes of these 186 frictional transients were proportional to the magnitudes of the logarithm of the velocity change, as 187 in RSF, with values of a and b in equation 1 of  $\sim 0.02$ , not far from values found in the lab. 188

We also observed that the granular model appeared be very similar to lab data during slide-hold 189 tests, in that the stress decay during the hold could be well-modeled by the Slip law for state evolution when using parameter values determined independently from velocity-step tests (Bhattacharya 191 et al., 2017, 2021). The results of our preliminary SHS simulations further indicated that the peak 192 stress upon the reslide exceeds the prediction of the Slip law, using the same parameters that fit 193 the hold well. This is similar to behavior observed in lab data (Bhattacharya et al., 2017). Note 194 that some previous studies also either conceptually or qualitatively showed that frictional healing 195 can occur during SHS tests as a result of compaction within the fault gouge (Sleep, 1995, 1997; 196 Nakatani, 1998; Chen et al., 2020). However, as we noted earlier, the simulations of Ferdowsi and 197 Rubin (2020) employed a stiffness that greatly exceeds those that can be achieved in the laboratory. 198 In the current study we also use stiffnesses more similar to laboratory tests. 199

#### **3** The computational model

We have performed the Discrete Element Method (DEM) simulations reported in this study us-201 ing the granular module of LAMMPS (Large scale Atomic/Molecular Massively Parallel Simulator), 202 a multi-scale computational platform developed and maintained by Sandia National Laboratories 203 (http://lammps.sandia.gov) (Plimpton, 1995). Our model is made of a packing of 4815 grains, of which there are 4527 in the gouge layer, and 288 in the top and bottom layers (Figure 1). 205 The grains in those top and bottom layers form rigid blocks parallel to the gouge layer and are used 206 to confine and shear the gouge. The grains in the rigid blocks all have a diameter d = 5 mm, whereas 207 those in the gouge layer have a polydisperse, Gaussian-like particle size distribution with diameters 208 (d) from 1 to 5 mm, with a mean diameter  $(D_{mean})$  of 3 mm. Grain density and Young's modulus 209 are modeled after glass beads (Table S1). The model domain is rectangular with periodic boundary 210 conditions applied in the x and y directions, with domain size  $L_x = L_y = 1.5L_z = 20 D_{mean}$ .

Figure 1. A visualization of the granular gouge simulation. Colors show the velocity of each grain in the x direction, averaged over an upper-plate sliding distance of  $D_{mean}$  during steady sliding at a driving velocity of  $V_i = 2 \times 10^{-4}$  m/s.

211

The system is initially prepared by randomly inserting (under gravity) grains in the simulation box with a desired initial packing fraction of ~0.5. The system is then allowed to relax for about  $10^6$ time steps, after which it is subjected to confining pressures  $\sigma_n = 5$  MPa. The confining pressure is applied for one minute, by which time the fast phase of compaction is completed. The confined gouge sample is then subjected to shearing at a desired driving velocity imposed by a linear spring attached to the top rigid plate, while the vertical position of the top wall is adjusted to maintain a constant confining pressure.

We model grains as compressible elastic spheres that interact with each other when they are in 219 contact via the Hertz-Mindlin model (Johnson, 1987; Landau & Lifshitz, 1959; Mindlin, 1949). The 220 full implementation of the granular physics model used here is presented in section 1 of the Supple-221 mentary Materials. The model essentially solves the linear vector equation F = ma for each grain, 222 along with its angular counterpart, with the simplification that the model does not track wave prop-223 agation through individual grains. In the simulations, slip occurs at grain contacts when the local 224 shear stress exceeds the specified (constant) local friction coefficient. Energy loss at contacts is char-225 acterized by the "restitution coefficient", which potentially varies from 0 (complete energy loss) to 1 226 (zero loss). The majority of the simulations in this study were performed with a very high restitution 227 coefficient of  $\epsilon_n = 0.98$ , corresponding roughly to performing experiments on gouge saturated with 228 dry air. However, we also have run a series of slide-hold simulations with a much lower restitution 229 coefficient of  $\epsilon_n = 0.3$ . Consistent with previous DEM studies at low sliding speeds, we find that the 230 adopted value of the restitution coefficient appears to have very little influence on the macroscopic 231 behavior of systems in the dense granular flow regime (Gaume et al., 2011; da Cruz et al., 2005; 232 Silbert et al., 2001; Ferdowsi & Rubin, 2020) (see also Figure 9 of this paper). The full details of the 233 granular module of LAMMPS are described in the LAMMPS manual and several references (Zhang & 234

Makse, 2005; Silbert et al., 2001; Brilliantov et al., 1996). Unless otherwise specified in this paper, all details of the present model, except for the values of pulling spring stiffness, are identical to the "default" model of Ferdowsi and Rubin (2020).

The relation of the velocity V in equations (1)–(3) to the granular simulations merits some discussion. In particular, this V is not the velocity of the upper (driving) plate. In laboratory experiments, slip parallel to the frictional interface is monitored between two points on opposite sides of, and some distance from, that interface, and the actual (inelastic) slip  $\delta$  is estimated from

$$\delta = \delta_{lp} - \delta_{el} = \delta_{lp} - \tau/k ;$$
  

$$\tau = k(\delta_{lp} - \delta) .$$
(4)

Here  $\delta_{lp}$  is the measured "load-point" displacement,  $\delta_{el}$  is the elastic distortion of the system between the monitoring points resulting from stress changes,  $\tau$  is the measured stress, and k is the elastic stiffness of the combined testing apparatus plus sample between the monitoring points (units of stress/distance). Taking the time-derivative of (4) leads to an estimate of the sliding speed as a function of measured quantities. Conceptually,  $\delta$  in lab experiments is often treated as occurring on a discrete plane, but, just as in our numerical simulations, it actually occurs over a region whose thickness is a priori unknown.

We treat our model output in the same way.  $\delta_{lp}$  is the displacement of the end of the spring at which the velocity is imposed, and  $\tau$  is the spring force divided by the 6 cm × 6 cm surface area of the driving plate. The effective stiffness k is given by treating the spring and gouge as being in series:

$$k = \frac{k_{sp}k_H}{k_{sp} + k_H} \tag{5}$$

where  $k_{sp}$  and  $k_H$  are the spring and gouge stiffness, respectively, and H denotes the gouge thickness. Equivalently, we could treat the "load-point" displacement  $\delta_{lp}$  as being the measured displacement of the driving plate, in which case  $k = k_H$  (showing, after insertion into (4) and differentiating, that V is not the velocity of the upper plate if the stress is changing, as this changes the elastic distortion of the gouge).

The shear modulus of the gouge layer can be estimated from the initially linear (nearly elastic) 254 portion of the loading stress-strain curve at the start of a steady-sliding test. In Fig. B1 of Ferdowsi 255 and Rubin (2020), we show the sensitivity of the gouge shear modulus to hold time duration in SHS 256 tests, and we find that at 5 MPa  $G_H \approx 270 - 310$  MPa regardless of hold time. From the value 257 of shear modulus  $G_H \approx 300$  MPa, the stiffness  $k_H$  can be determined as  $k_H = G_H/H = 7.3 \times 10^9$ 258 Pa/m, where H = 0.04 m is the gouge thickness. We can further determine  $k_{sp}$  in Pa/m from the 259 spring stiffness input,  $k_{pull}$ , in LAMMPS in units of N/m, by dividing  $k_{pull}$  by the sample surface area. We use 3 pulling spring stiffnesses:  $k_{pull} = 1 \times 10^{10}, 8 \times 10^5, 2.7 \times 10^4$  N/m corresponding 260 261 to dimensionless system stiffness  $\bar{k}_d \equiv kD_c/(b\sigma) \approx 425$ , 12, 0.4, respectively, where the " $\approx$ " sign 262 indicates that the values of the normalizing constants b and  $D_c$ , determined from fitting simulated 263 velocity-step tests, are known only to within about 10%. The dimensionless stiffness  $k_d \approx 425$  rep-264 resents the approximate upper bound for what we can achieve;  $k_{pull} = 10^{10}$  N/m is large enough that essentially all the elastic compliance comes from the gouge. The dimensionless system stiffnesses 266 of  $k_d \approx 12$  and 0.4 were chosen to be close to the values of k in the SHS experiments performed on 267 the rotary shear apparatus of Beeler et al. (1994), to which we compare some of our granular model 268 observations. After performing the granular simulations reported in this work, our estimates of  $k_d$ for those lab data, based on the analysis of Bhattacharya et al. (2021), were reduced by 1/3 from 270 their initial values, to  $k_d \approx 8$  and 0.27, so the match with our simulations is not exact. For analysis 271 of our simulation data we used values of  $D_c = 1.77D_{mean} = 0.0053$  m, a = 0.0247, and b = 0.0178272 which were obtained from velocity-stepping simulations (Ferdowsi & Rubin, 2020). 273

Friction in our simulations is defined as the ratio of the shear to normal force exerted on the upper rigid block by the gouge grains in contact with it. If accelerations of the upper plate are unimportant, this shear force can be equated with the force applied by the pulling spring in (4). If the plate velocity suddenly changes to or from  $\sim 1$  m/s, this assumption is violated and wave propagation

within the gouge must be considered (Ferdowsi & Rubin, 2020, Appendix B). The SHS simulations 278 reported here were run with initial steady-state velocities of  $V_i = V_{lp} = 2 \times 10^{-3}$ ,  $2 \times 10^{-2}$ , and 279  $10^{-1}$  m/s, and in most simulations we used a reslide velocity equal to the initial velocity. However, 280 in a small number of cases we changed the reslide velocity to search for deviations from the pre-281 dictions of existing RSF equations; any such deviations would be relevant to models of earthquake 282 nucleation. We also performed a series of slide-hold simulations at the smaller initial sliding veloc-283 ity of  $V_i = 2 \times 10^{-4}$  m/s. In laboratory experiments, the sliding velocity is typically on the order 284 of  $1 - 10 \mu$ m/s; however, running simulations at such velocities is not yet possible with the DEM 285 method within reasonable computational costs, provided one uses grain elastic properties and den-286 sities appropriate for quartz-like materials. Our fully parallelized simulations at sliding velocities of  $V_i = 2 \times 10^{-2}$ ,  $2 \times 10^{-3}$  and  $2 \times 10^{-4}$  m/s, took about a few days, two weeks, and six weeks of real 288 time, respectively, to achieve steady-state friction on Princeton's PICSciE's computational cluster. 289 The longest holds took 5 months. 290

To assess the importance of our deviation from lab-like parameters, we turn to dimensionless 291 ratios. The sliding velocity enters only one – the Inertial number, a critical parameter in granular 292 flows, defined as  $I_n \equiv \dot{\gamma} D_{mean} \sqrt{\rho/P} \approx V(D_{mean}/H) \sqrt{\rho/P}$ , where  $\dot{\gamma}$  is the local shear rate, the 293 approximate equality is appropriate for our loading geometry (we do not see localization in our 294 system), P is the confining pressure (synonymous with the normal stress in these simulations), and  $\rho$ 295 and  $D_{mean}$  are the density and mean diameter of grains, respectively. The inertial number measures 296 the ratio of the inertial forces of grains to the confining forces acting on those grains, such that 297 small values  $(I_n \leq 10^{-3})$  correspond to the dense, quasi-static regime of shearing that we desire to 298 model (da Cruz et al., 2005; Forterre & Pouliquen, 2008). The SHS simulations reported here with 299  $V_i = 2 \times 10^{-3}$  to  $10^{-1}$  m/s have inertial numbers during steady sliding satisfying  $\sim 10^{-6} \leq I_n \leq 10^{-4}$ , 300 all in this quasi-static regime. Ferdowsi and Rubin (2020) explore the range ~  $10^{-7} \leq I_n \leq 10^{-3}$ 301 during velocity-step tests, and find no significant variation in the RSF parameter values. There is no 302 a priori expectation that the RSF parameters will begin to vary at still lower  $I_n$ , but of course one does 303 not know this, and testing for systematic changes with  $V_i$  provides the motivation for performing 304 SHS tests at a range of achievable sliding velocities within the quasi-static regime. 305

Confining pressure enters the Inertial number discussed above as  $P^{-1/2}$ , and also the "dimen-306 sionless pressure"  $\bar{P} = (P/E)^{2/3}$ , where E is Young's modulus (50 GPa in our simulations).  $\bar{P}$  is 307 a measure of the grain strain at the imposed confining pressure; the 2/3 power is appropriate for 308 contacting elastic spheres (Hertzian contacts). With P = 5 MPa,  $\bar{P} = 2 \times 10^{-3}$  in our simulations. 309 Ferdowsi and Rubin (2020) explored values  $0.7 \times 10^{-3} \leq \bar{P} \leq 6 \times 10^{-3}$  (1 < P < 25 MPa), and found 310 only modest variations in the RSF parameter values. Rather than tailor our values of  $\overline{P}$  to individual 311 experiments, we chose to maintain the default value of P = 5 MPa in Ferdowsi and Rubin (2020), 312 and rely on their observation that the RSF parameters do not seem to be very sensitive to this choice. 313

In contrast, there is reason to believe that the choice of system stiffness in our slide-hold and 314 SHS simulations is quite important. For the longest (load-point) holds conducted by Beeler et al. 315 (1994), one can estimate (from their reported stress drops and stiffnesses) that there was  $\sim 2.4 \ \mu m$ 316 of accumulated slip in their high-stiffness case and  $\sim 16 \ \mu m$  of slip in their low-stiffness case. For 317  $D_c \sim 2\mu m$  (Bhattacharya et al., 2021) this corresponds to roughly  $1.2D_c$  and  $8D_c$  of slip. Given the 318 potential importance of slip on the order of  $D_c$  to state evolution, this difference is quite significant. 319 For a complete list and discussion of the governing dimensionless variables of the model, see Ap-320 pendix A of Ferdowsi and Rubin (2020). As one last point, we note that reducing all length scales 321 (the grain size and all model dimensions) by the same factor, while keeping  $V_i$  the same, results in 322 simulations that are dimensionally identical. 323

#### **4 Results and discussion**

#### 325 4.1 General considerations

Before proceeding to the results of the granular simulations, it is worth considering what it means to "compare" our results to laboratory experiments. The ratio a/b for the granular simulations,

determined from simulated velocity steps, is  $\sim$ 1.4, and may be fixed by our choice of spherical 328 particles, Gaussian-like grain size distribution, and the tangential and normal contact laws we have 329 adopted (for example, Ferdowsi and Rubin (2020) found that a more exponential-like grain size 330 distribution gave rise to simulations with values of a/b much closer to 1; we did not pursue those here 331 because they were noisier and would have required even larger system sizes and more computational 332 resources to see clear signals). The value  $a/b \sim 1.4$  is slightly high by lab standards, and we are 333 not aware of lab experiments that push surfaces with such values far enough from steady state to be useful for constraining models of state evolution. Therefore we do not necessarily expect our 335 granular simulations to match any particular lab experiment. Nonetheless, we were able to claim that 336 the simulations successfully capture the phenomenology of laboratory velocity-step experiments. 337 This phenomenology entails that the amplitudes of the changes in friction with velocity and state are 338 proportional to the logarithm of the velocity step (amplitudes controlled in RSF by the parameters 339 a and b), and that friction evolves to its future steady state value over a characteristic slip distance 340  $(D_c)$ , independent of the size or sign of the velocity step. Because, by design, these attributes of lab 341 experiments are replicated by the Slip version of the RSF equations, it was convenient to use Slip 342 law fits to our simulation output to determine the values of a, b, and  $D_c$  that fit our data well (note 343 that absent some conceptual model for friction, we could not even have made the statement above 344 that in our simulations " $a/b \sim 1.4$ "). 345

For slide-hold tests the situation is more complicated, because it is less obvious what the "phe-346 nonomenology" of laboratory holds is. Here we made more essential use of comparisons between our simulations and the predictions of the Aging and Slip laws for state evolution, on the one hand, 348 and comparisons between the Aging and Slip laws and laboratory experiments, on the other. Bhat-349 tacharya et al. (2017; 2021) showed that the stress decay during laboratory holds was fit reasonably 350 well by Slip law simulations, using parameter values determined independently from velocity steps, and that the Aging law, with its time-dependent healing, predicted too little stress decay. Because 352 these features of the lab data were replicated by our numerical simulations, we used this indirect 353 comparison (granular simulations to RSF / RSF to lab data) to claim that the granular simulations 354 also seemed to do a good job matching laboratory slide-hold experiments (although, as we noted previously, the comparison in Ferdowsi and Rubin (2020) was made using a system stiffness that 356 exceeds those achievable in the lab). For SHS tests, the salient phenomenology is that the peak 357 friction upon resliding increases nearly linearly with the logarithm of hold time. For the Aging law, 358 which was designed to produce this behavior, the slope of this increase (suitably normalized) is the 359 RSF parameter b, whereas in lab experiments it seems to be variable but roughly a factor of 2 smaller 360 (see Section 4.3). So although in this case we could "compare" the slope in our simulations directly 361 to lab data without seeming to reference the Aging law, in fact by choosing to compare the slope to 362 b we are implicitly making use of the Aging law. That is, absent some moderately successful model 363 prediction, it is not apparent what we should be comparing the slope of our healing relation to. 364

#### 4.2 Slide-hold simulations

365

In this section we present the slide-hold (SH) behavior of the granular model. Since individual simulations tend to be somewhat noisy, all simulation signals presented in this manuscript are averaged over eight different realizations (initial grain arrangements) of the model, all subjected to the same boundary conditions. Friction is defined as the ratio of shear to normal stress  $\tau/\sigma$ , where  $\tau$  is the shear force per unit area exerted by the gouge particles on the upper (driving) plate, and  $\sigma$  is the normal force per unit area on the upper plate.

Figures 2a-c show the variation of normalized friction with normalized hold time for SH tests, with initial sliding velocities of  $V_i = 2 \times 10^{-3}$ ,  $2 \times 10^{-2}$ , and  $10^{-1}$  m/s shown by the cyan, blue, and black curves, respectively. Panel (a) shows the results of simulations run with system stiffnesses  $\bar{k}_d \approx 425$ , while panels (b) and (c) show simulations with system stiffness  $\bar{k}_d \approx 12$  and  $k_d \approx 0.4$ , respectively. Based on the indicated reductions in friction and the system stiffnesses, the longest holds in these simulations correspond to total (inelastic) slips within the gouge layer of roughly (from most to least stiff)  $0.04D_c$ ,  $D_c$ , and  $10D_c$ .

Lowering the stiffness delays the onset of stress decay because a given stress reduction then 379 requires a longer slip distance; at constant sliding velocity, elasticity dictates that the normalized 380 friction change  $\Delta \mu/b$  reaches -1 when  $t_{hold}/(D_c/V_i) = \bar{k}^{-1}$ , which is roughly when the stress trajectories in Figure 2 leave their initial plateau (the Slip law predictions for  $\bar{k}_d \approx 12$  and  $\bar{k}_d \approx 0.4$ 382 have been included in panel (a) for reference). From dimensional analysis, standard RSF (equations 383 1–3 with constant parameter values) predicts that the curves for the same k but different  $V_i$  overlap 384 identically when plotted versus dimensionless hold time  $\bar{t}_{hold} \equiv t_{hold}/(D_c/V_i)$ . Our simulations at the three sliding velocities with  $\bar{k}_d \approx 425$  show a stress decay response that is not exactly the same, 386 but they are nevertheless similar to each other within their standard deviations. The stress decay 387 response for the three velocities differ more significantly at the lower stiffnesses of  $k_d \approx 0.4$  and 12. 388

Figures 2a-c also include the predictions of the Aging and Slip laws for the stiffnesses used 389 in the granular model. These predictions are obtained using the RSF parameter values determined 390 independently from Slip law fits to simulated velocity steps performed on the identical granular 391 system (Ferdowsi & Rubin, 2020). For  $\bar{k}_d \approx 425$ , the stress decay of the granular model is in 392 excellent agreement with the Slip law prediction. There is also reasonable agreement for the lower 393 stiffnesses of  $k_d \approx 0.4$  and 12, where the Slip law prediction generally lies between the curves for 30/ the different  $V_i$  (we return to the differences between the different  $V_i$  below). In contrast, for the 395 two larger stiffnesses, where the Aging- and Slip-law predictions differ, the Aging-law significantly 396 underestimates the stress decay at long hold times. The shallowing slope of the stress decay for 397 the Aging law results from its prediction of continual state evolution,  $\theta \approx 1$  in equation 2, even at vanishing slip rates. Analytically, the slope of the stress decay at long hold times for the Aging law 300 (with a/b > 1) is (1-a/b) when plotted vs.  $\ln(\bar{t}_{hold})$ , and 2.3(1-a/b) when plotted vs.  $\log_{10}(\bar{t}_{hold})$ , 400 independent of the system stiffness (Bhattacharya et al., 2017, Appendix C). For the Slip law, the 401 long-time slope in general depends upon stiffness, but in the "infinite-stiffness limit" it is 2.3(-a/b)when when plotted vs.  $\log_{10}(\bar{t}_{hold})$  (Bhattacharya et al., 2017), which for the parameter values of 403 our granular simulations is 3.6 times larger. All 3 initial velocities for  $\bar{k} \approx 425$  in Figure 2a, and the 404 corresponding Slip-law prediction, have this "infinite-stiffness limit" slope. For  $\bar{k}_d = 0.4$ , there is 405 sufficiently little reduction in slip speed that the predictions of the Aging and Slip laws are extremely 406 similar. 407

Because our initial sliding velocities are higher than those typically used in laboratory slide-408 hold experiments, it is important to assess any systematic trends with  $V_i$  in the granular simulations. 409 At the highest stiffness ( $\bar{k} \approx 425$ ), the curves for the different V<sub>i</sub> tend to weave around the Slip-law 410 prediction, but they all end up with the same (Slip-law) slope at the longest hold times. At short 411 hold times for  $\bar{k} \approx 12$  and 0.4, there do not seem to be trends that are monotonic with  $V_i$ , with the 412 slowest velocity  $(2 \times 10^{-3} \text{ m/s})$  plotting between the two larger velocities. However, at the longest 413 hold times in Figure 2b ( $\bar{k} \approx 12$ ), there is a systematic trend of lower stress with lower  $V_i$ . Whether 414 this trend would persist to longer hold times is not known. 415

An example of frictional behavior during a laboratory slide-hold experiment on rock is shown 416 in Fig. 2d, from Bhattacharya et al. (2021). The experiment was performed on a granite sample with 417 initial sliding velocity  $V_i = 0.316 \ \mu$ m/s, system stiffness  $k_d \approx 8$ , and confining stress 25 MPa. The 418 Aging and Slip law predictions for the experiment are shown with green and pink lines, respectively. 419 These predictions, similar to the RSF predictions for the granular model, are obtained using the RSF 420 parameter values determined independently from Slip law fits to velocity-stepping experiments on 421 the same sample. Overall, as with the fits to the granular simulations, they indicate that the Aging 422 423 law underestimates the stress decay in the lab at long hold times, while the Slip law provides a very good prediction of the behavior. Comparing the behavior of both the lab data and the granular model 424 to the Aging and Slip law predictions, especially Figures 2b and 2d with close to the same stiffness, 425 we conclude that although the stress decay in the simulations is not strictly log-linear as for the lab 426 data, the granular model qualitatively captures the stress decay observed in laboratory slide-hold 427 tests. 428

The stress decay during slide-hold protocols clearly rules out the Aging law for the evolution of state in both the granular model and laboratory experiments. This is despite the fact that logtime fault-normal compaction is almost universally observed during laboratory holds under room-

Figure 2. The slide-hold behavior: The cyan, blue, and black lines in panels (a-c) show the variation of friction coefficient, normalized by the RSF parameter b, as a function of normalized hold time, for granular slide-hold simulations with prior sliding velocities  $V_i$  of  $2 \times 10^{-3}$  (cyan),  $2 \times 10^{-2}$  (blue),  $10^{-1}$  (black) m/s. Panels (a), (b), and (c) show the behavior of the systems with stiffness  $\bar{k}_d \approx 425$ , 12, and 0.4, respectively. The pink and green lines in panels (a-c) further show the predictions of the Slip and Aging laws, respectively, using the RSF parameters ( $D_c = 0.0053$  m, a = 0.0247, b = 0.0178) determined independently from Slip-law fits to velocity-step tests performed on the same model (Ferdowsi & Rubin, 2020). The predictions of the Slip and Aging laws are shown with different line styles for different system stiffnesses (the Slip law predictions for  $\bar{k} = 12$  and 0.4 are included in panel (a) only for reference). Granular simulation results in panels (a-c) are averaged over 8 different realizations (initial grain arrangements) subjected to the same imposed loading conditions. Black, blue, and cyan lines show the mean behavior of the realizations for each system, and the width of the gray, blue, and cyan shades around each line shows the 2-sigma deviations. The confining pressure in all simulations is 5 MPa. (d) The blue line shows the variation of friction coefficient, normalized by the RSF parameter b, as a function of normalized hold time, for an experiment performed in the Tullis rotary shear apparatus at Brown University on a granite sample with prior sliding velocity  $V_i = 0.316 \ \mu m/s$ . The system stiffness for this experiment is  $\bar{k}_d \approx 8$ , and the confining stress is 25 MPa. As in panels (a-c), the pink and green lines show predictions of the Slip and Aging laws, respectively, using the RSF parameters ( $D_c = 2 \mu m$ , a = 0.013, b = 0.016) obtained from Slip-law fits to velocity-step tests on the same experimental sample. We used the same RSF parameters to calculate the dimensionless stiffness  $\bar{k}$  for the lab data.

Figure 3. Gouge compaction during slide-holds: The cyan, blue, and black lines in panels (a) & (b) show the variation of gouge compaction, normalized by the RSF characteristic slip distance  $D_c$ , as a function of normalized hold time, for granular slide-hold simulations with prior driving velocities  $V_i$  of  $2 \times 10^{-3}$  (cyan),  $2 \times 10^{-2}$  (blue), and  $10^{-1}$  (black) m/s. Panel (a) shows the behavior for stiffnesses  $\bar{k}_d \approx 425$  and 12, while panel (b) shows the behavior of stiffness  $\bar{k}_d \approx 0.4$ . The widths of the gray, blue, and cyan shades around the mean behavior lines indicate 2-sigma deviations. (c) The pink and green lines show the evolution of log(state) under the Slip and Aging laws, respectively, using the RSF parameters determined independently from Sliplaw fits to velocity-step simulations (Ferdowsi & Rubin, 2020). The state evolutions are scaled by the factor  $-d(H_{ss}/D_c)/d\log\theta \approx 0.035$  (Fig. 2c in Ferdowsi and Rubin (2020)), where the  $H_{ss}$  is the steady-state thickness of the granular layer (see text for discussion). Different line styles correspond to different system stiffnesses as described in the legend. The filled and empty dots in all panels show the change in gouge thickness during hold experiments on a granite sample reported by Beeler et al. (1994), who used two different ( $\bar{k}_d \approx 8$ and 0.27) machine stiffnesses. The dots are filled or empty in panels (a) and (b) depending on the machine stiffness that is most appropriate to compare the granular model behavior to in that panel. An estimated slipweakening distance  $D_c \approx 2\mu m$  is used to normalize compaction data in laboratory experiments (Bhattacharya et al., 2021). The lab experiments with stiffness  $\bar{k}_d \approx 0.27$  and 8 were performed with sliding velocities  $V_i = 1$  $\mu$ m/s and 0.32  $\mu$ m/s, respectively. Both low and high stiffness laboratory experiments were performed at 25 MPa confining pressure.

humidity conditions. This compaction is thought to be consistent with an Aging law-like evolution 432 of state; that is, in theoretical justifications of the Aging law, the same mushrooming of highly-433 stressed contacts that is considered to be responsible for log-time increase of true contact area and 434 frictional strength, would also lead to log-time compaction (Berthoud et al., 1999; Sleep, 2006). 435 The same argument would suggest that if the stress data during holds is well modeled by the Slip 436 law, with its relative lack of state evolution, the fault-normal compaction would be much less. This 437 potential conflict between the stress and fault-normal displacement data from laboratory holds was 438 noted previously by Bhattacharya et al. (2017). 439

In our previous work, we observed that in addition to matching the stress decay during labora-440 tory holds, the granular model led to log-time reduction in gouge thickness for  $\bar{k}_d \approx 425$  (Ferdowsi 441 & Rubin, 2020). Here we examine the changes in gouge thickness during slide-holds using stiff-442 nesses more appropriate for lab experiments. Figure 3a shows the gouge compaction with hold time 443 in the granular model with stiffnesses  $\bar{k}_d \approx 425$  and 12, in comparison to the gouge compaction 444 observed in the laboratory for two system stiffnesses  $\bar{k}_d \approx 8$  (filled circles) and 0.27 (lab data from 445 Beeler et al. (1994), as reported by Bhattacharya et al. (2017)). The lab experiments were performed 446 in a rotary shear apparatus, so there is no need to correct for sample dilation/compaction due to 447 a Poisson effect as the loading stress changes (Beeler et al., 1996). The gouge compaction in the 448 granular model with the lower stiffness  $k_d \approx 0.4$  is shown separately in Fig. 3b for clarity, where 449 now the lab data for  $k_d \approx 0.4$  are shown as filled circles. These plots indicate that the magnitude 450

of gouge compaction in the granular model is in general agreement with laboratory observations, 451 after both are normalized by their appropriate value of  $D_c$ . For the granular simulations this is the 452 sensible normalization; Ferdowsi and Rubin (2020) found that the ratio of gouge thickness changes 453 to  $D_c$  was independent of the nominal gouge thickness over the range they explored. For the lab 454 data, normalization by  $D_c$  is intended to account for the fact that deformation is typically localized 455 over a layer of unknown thickness; inherent in this approach is the assumption that both slip and 456 compaction are concentrated within this layer. Together, panels (a) and (b) show that gouge compaction in the granular model is much less strongly dependent on system stiffness than is the stress 458 decay, and that the normalized rate of compaction with log time is close to that of the lab data (most 459 obviously for the simulation with lowest stiffness, panel (b), which is also the simulation for which 460 the compaction is most nearly log-linear). The lab data show more of a stiffness-dependent offset 461 along the time axis than do the simulations, although the simulations with the lowest  $V_i$  of  $2 \times 10^{-3}$ 462 m/s show a modest offset of the proper sign. 463

The relatively weak dependence of the compaction rate on stiffness in the granular simulations 464 is reminiscent of the Aging-law prediction for the evolution of state  $\theta$ , because for long Aging-law 465 holds  $\theta \sim 1$ , independent of all else. Fig. 3c shows the evolution of log(state) as predicted using 466 the RSF Aging and Slip laws (in green and red, respectively), for the three stiffnesses used in the 467 granular model. To plot log(state) on the same axis as compaction, we use the linear relation between 468 steady-state gouge thickness and log velocity found by Ferdowsi and Rubin (2020), combined with 469 the RSF relation that at steady state velocity is inversely proportional to state. That is, we multiply the computed change in log(state) by the factor  $-d(H_{ss}/D_c)/d\log\theta$ , found to be ~0.035 in Figure 471 2c of their paper, where  $H_{ss}$  is the steady-state thickness of the gouge layer. The agreement between 472 this Aging law prediction and the lab data, and from comparison to Figures 3a and 3b the agreement 473 between the granular simulations and the lab data, is quite remarkable. The evolution of state under the Slip law for the lowest stiffness is, as with the stress decay, very similar to that for the Aging law. 475 However, as the system stiffness increases, the evolution of state under the Slip law significantly 476 decreases because the amount of slip decreases. Translating this state evolution to fault-normal 477 compaction as in Figure 3c, the prediction would be that compaction for the Slip law should be 478 strongly stiffness-dependent, completely unlike compaction in the simulations and in the lab data. 479 All of this serves to emphasize the point that while stress during the holds is fit well by the Slip law, 480 compaction during the holds is fit much better by the Aging law prediction of state evolution. 481

#### 482

#### 4.3 Slide-hold-reslide simulations

We have thus far presented a detailed discussion of the slide-hold behavior of the granular 483 simulations. A main motivation for conducting SHS experiments on rock is to better understand 484 the fault healing that occurs during interseismic intervals, healing that is necessary for repeated 485 earthquakes to occur on the same section of fault. This healing historically has been measured 486 by the peak stress  $\Delta \mu_{peak}$  upon resliding following a hold (see the inset in Figure 4a), under the 487 assumption that little state evolution occurs in the short time or slip distance between the start of 488 the reslide and the peak stress (we leave aside here the question of whether room temperature and 489 humidity experiments are relevant to natural faults at depth). Because the Aging law embodies fault 490 healing (state evolution) with time even in the absence of slip, for the same parameter values it generates more healing during holds than the Slip law. More diagnostically, sufficiently long hold 492 times lead to  $V\theta/D_c \ll 1$ , so from equation 2 for the Aging law,  $\dot{\theta} \approx 1$ . This means that for long hold 493 times the rate of healing with log hold time is independent of how much slip accumulates during 101 the hold, and hence it is independent of the elastic stiffness of the loading system (Beeler et al., 495 1994; Bhattacharya et al., 2017). These authors further showed that the Aging law predicts that the 496 reduction in log(state) between the start of the reslide and peak stress is independent of hold duration, 497 and hence that the predicted change in peak friction with log hold time,  $d\Delta\mu_{peak}/d\ln(\bar{t}_{hold})$ , equals 498 the RSF parameter b (equation (1); note that at peak stress  $d\tau/dt = 0$ , so from elasticity the sliding 499 velocity equals the load-point velocity). This property was exploited by Beeler et al. (1994), who ran 500 lab experiments with two loading machine stiffnesses and found that, indeed, for long hold times, 501 the rate of healing was independent of stiffness. Bhattacharya et al. (2017) later showed that, for 502 the two stiffnesses and hold durations of those experiments, the same stiffness-independent rate of 503

parameters do not include the ratio of a/b appropriate for our granular simulations.

**Figure 4.** Frictional healing in the granular model: Solid circles show  $\Delta \mu_{peak}$  normalized by the RSF parameter *b* (estimated from velocity steps), as a function of normalized hold time in granular slide-hold-slide simulations at  $V_i = 2 \times 10^{-3}$ ,  $2 \times 10^{-2}$ , and  $10^{-1}$  m/s. Panels (a), (b), and (c) show the results for system stiffnesses of  $\bar{k}_d \approx 425$ , 12, and 0.4, respectively. Error bars are 2-sigma deviations of 8 different realizations. The green and pink lines in each panel show the predictions of the Aging and Slip laws, respectively, for that specific system stiffness using the RSF parameters obtained from velocity-step tests. The inset in panel (a) shows the schematic of a slide-hold-slide test and the definition of frictional healing,  $\Delta \mu_{peak}$ . (d) Frictional healing in the lab: Solid circles show  $\Delta \mu_{peak}$  as a function of normalized hold time, in slide-hold-slide experiments performed on a granite sample at 25 MPa confining pressure (Beeler et al., 1994) with machine stiffness  $\bar{k}_d \approx 0.27$  and 8, at sliding velocities of  $V_i = 1 \ \mu m/s$  and  $0.32 \ \mu m/s$ , respectively. The green dashed lines show the evolution of frictional healing,  $\Delta \mu_{peak}$ , normalized by the RSF parameter b = 0.0109 (estimated from the slope of healing vs. time data in this figure) with a - b = -0.0027 (Bhattacharya et al., 2017) and  $D_c = 2 \ \mu m$  (Bhattacharya et al., 2021). These parameters result in normalized stiffness values of  $\bar{k}_d \approx 0.472$  and 14.165 for the Aging law predictions in this plot.

511

512

It is well established from decades of laboratory experiments on rock and gouge that the peak friction upon resliding increases nearly linearly with log hold time (J. H. Dieterich, 1972; Beeler et al., 1994; Baumberger & Caroli, 2006; Marone & Saffer, 2015; Carpenter et al., 2016). The only study of which we are aware that compares the observed rate of increase to the Aging law prediction,  $d\Delta\mu_{peak}/d\ln(\bar{t}_{hold}) = b$ , using values of *b* determined independently from velocity-step tests, is the combined work of Ikari et al. (2016) and Carpenter et al. (2016) on natural and synthetic gouge materials. Excluding their synthetic clay gouges, for which our granular simulations with spherical grains are likely inappropriate, Ikari et al. (2016) found slopes mostly in the range of ~0.3*b* to 0.7*b*. Beeler et al. (1994) found  $d\Delta\mu_{peak}/d\ln(\bar{t}_{hold}) \sim 0.01$  for their granite sample, close to the expected value of *b* for granite, but a slope of ~0.004 for quartzite, probably a factor of ~2 lower than the expectation for *b*. Marone and Saffer (2015) found slopes of ~0.0035, plus or minus several tens of percent depending upon  $V_i$ , values that seem within the range of Ikari et al. (2016).

Beyond this, results seem to be limited to single studies. As mentioned previously, Beeler et al. (1994) showed that the rate of frictional strengthening  $d\Delta\mu_p/d\ln(\bar{t}_{hold})$  was independent of system stiffness, and interpreted this as suggesting that frictional healing depends upon time rather than slip. Marone and Saffer (2015) showed that the rate of frictional strengthening in their synthetic gouge samples depended upon  $V_i$ , increasing by nearly a factor of 2 over the range 1–100  $\mu$ m/s, indicative of a velocity-dependence of the RSF parameters or a characteristic velocity in the governing equations not captured by the standard RSF equations (1)–(3). However, over the same range of velocities Carpenter et al. (2016) found no significant dependence upon  $V_i$ .

Here we present results of granular SHS simulations for a wide range of hold times at  $V_i$  = 526  $2 \times 10^{-3}$ ,  $2 \times 10^{-2}$ , and  $10^{-1}$  m/s. Panels (a), (b) and (c) in Fig. 4 show the changes in peak stress 527 with hold time for simulations performed with stiffnesses  $\bar{k}_d \approx 425$ , 12, and 0.4, respectively. 528 These panels show that for the longest holds, the peak stress increases nearly logarithmically with 529 hold time, in qualitative agreement with laboratory rock friction data. In each panel the green and 530 red lines indicate the predictions of Aging and Slip law simulations, respectively, using parameter 531 values determined from Slip law fits to our velocity-step simulations. For each stiffness (each panel) 532 the slope of the green Aging-law prediction is equal to b, when plotted vs.  $\ln(\bar{t}_{hold})$  rather than 533  $\log_{10}(\bar{t}_{hold})$ . Comparison to the granular simulations show that the slope of the log-time healing ranges from  $\sim 0.5b$  to b, also in qualitative agreement with laboratory data. However, unlike the data 535 of Beeler et al. (1994), the rate of healing at long hold times differs by nearly factor of 2 between 536 the simulations with  $k \approx 12$  and  $k \approx 0.4$ . In addition, unlike the data of Marone and Saffer (2015), 537 but similar to that of Carpenter et al. (2016), there is not an obvious dependence of this slope upon 538  $V_i$ . 539

In contrast to the Aging law, the Slip law simulations produce a strongly stiffness-dependent rate of frictional healing. For  $\bar{k} \approx 425$ , there is so little slip that there is almost no state evolution (healing). For  $\bar{k} \approx 0.4$ , there is so much slip that the rate of healing is not much less than that for the Aging law. Note that the healing in the granular simulations is more than that predicted by the Slip law when  $\bar{k}_d \approx 425$  and 12, but less than predicted when  $\bar{k}_d \approx 0.4$ . Thus, the observation of Ferdowsi and Rubin (2020) that for  $\bar{k} \approx 425$  the healing in the granular model lies between the Aging and Slip law predictions is not generalizable to all stiffnesses.

The laboratory rock friction data of Beeler et al. (1994) are shown in Figure 4d. Only (a - b)was determined in this study, so for the Aging law simulations shown we take  $D_c = 2\mu m$  determined for the same sample by Bhattacharya et al. (2021), and fix b = 0.0109 to match the slope of the lab healing curves. This comparison shows that while healing in the lab data leads that of the Aging law prediction (for the higher lab stiffness) or is in general agreement with it (for the lower stiffness), healing in the granular simulations generally lags the corresponding Aging-law prediction. This comparison should be extended to experiments where the RSF parameters were determined independently.

In laboratory slide-hold-slide experiments, the reslide is accompanied by dilation of the gouge 555 layer, dilation that continues monotonically beyond the moment of peak stress to the future steady-556 state thickness. We observe the same behavior in our simulations. Figures 5a to 5c show the variation 557 of dilation at peak stress in the granular model for the sliding velocities  $V_i = 0.1, 0.02$ , and 0.002 558 m/s, respectively, for each of the 3 stiffnesses we used. This dilation increases nearly linearly with 559 log-hold time. For the simulations with  $V_i = 0.1$  and 0.02, the magnitude of this dilation (at large 560 normalized hold times) decreases with increasing system stiffness, opposite to the trend seen in the 561 lab data of Beeler et al. (1994) and shown in Fig. 5d. The trend of the change in dilation at peak 562 stress with system stiffness for the simulations with  $V_i = 0.002$  m/s is in better agreement with the 563 laboratory observations in Fig. 5d. We further normalize the dilation at peak stress by the amount 564

**Figure 5.** The variation of normalized dilation at peak stress ( $\Delta H_{\text{peak stress}}/D_c$ ) versus hold time, following reslides for the granular model with sliding velocities of (a)  $V_i = 0.1 \text{ m/s}$ , (b)  $V_i = 0.02 \text{ m/s}$ , and (c)  $V_i = 0.002 \text{ m/s}$ . The amount of dilation is defined as the change in gouge thickness between the end of the hold and the moment of peak stress, as in Fig. B1 of Bhattacharya et al. (2017). The simulations are performed at three different stiffnesses and 5 MPa confining stress. (d) dilation at peak stress ( $\Delta H_{\text{peak stress}}$ ) in the lab (data of Beeler et al. (1994)), (e) The ratio of dilation at peak stress ( $\Delta H_{\text{peak stress}}$ ) to compaction at the end of the corresponding hold in the granular model (circles) and in the lab (diamonds) (data of Beeler et al. (1994)). The lab data shown in panels (d) and (e) are reported by Bhattacharya et al. (2017).

of compaction at the end of the corresponding hold. The ratio of dilation/compaction that results from this analysis is shown in Fig. 5e, plotted alongside the same quantity observed in the lab data of Beeler et al. (1994). Comparing the lab data to the simulations conducted at roughly the same stiffnesses, we find that the relative slopes of the log-linear portion of the dilation and compaction in both the simulations and lab (normalized hold times  $\geq 10^1$ ) are in the fairly narrow range  $\sim 0.4-0.5$ , and are there therefore in qualitative agreement with each other. For shorter hold times, both the lab data and simulations show considerable scatter.

Among other features observed in slide-hold-slide tests, Figure 5 of Marone and Saffer (2015) 572 suggests that the slip-weakening distance following the peak stress upon resliding increases with 573 hold duration. This feature is inconsistent with the Slip law prediction, but we see evidence of 574 similar behavior in our SHS simulations. Figures 6a & b show the variation of friction coefficient 575 with sliding distance in the reslide portion of SHS simulations performed after a range of hold times, 576 for  $V_i = 0.1$  and 0.02 m/s, referenced to the steady-state friction value at  $V_i$ . These signals show 577 (more obviously in Fig. 6a) that the slip distance to peak friction increases with increasing hold time, 578 as for the Marone and Saffer (2015) data (their Figure 12). Panels c-d in Fig. 6 also include the Slip 579 law prediction for a one-order velocity-step increase, normalized to the same peak-residual value as 580 the reslide friction signals. These two panels more clearly demonstrate the increase in weakening 581 distance with hold time. The reslides at shorter holds have a weakening distance,  $D_c$ , roughly equal 582 to the distance observed in the velocity-steps. At longer hold times,  $D_c$  further increases, although 583

**Figure 6.** The variation of friction  $(\mu - \mu_{ss})$  versus slip distance (Slip /  $D_c$ ) during the reslide portion of slide-hold-slide simulations, for different values of normalized hold time  $t_{hold}/(D_c/V_i)$  and sliding velocities of (a)  $V_i = 0.1$  m/s and (b)  $V_i = 0.02$  m/s. Panels (c) and (d) show the signals in panels (a) and (b) with values normalized by the peak friction value in each simulation. All simulations are performed with stiffness  $\bar{k}_d \approx 425$  at 5 MPa confining stress. The black dashed line in panels (c) and (d) show the Slip law predictions for a one order of magnitude velocity-step increase, using the RSF parameters that provide good fits to velocity steps of various sizes performed with the granular model (Ferdowsi & Rubin, 2020). The Slip law prediction is scaled to the same peak-residual scale as the granular simulation data in the panels. The lines are added to show that the slip-weakening distance  $D_c$  increases with hold duration from a minimum value that is consistent with the value appropriate for velocity steps.

the amount of increase in  $D_c$  in the granular model appears to be less than that observed in lab data. Sleep et al. (2000) proposed a model in which delocalization of slip within a granular layer during a hold led to an increase in the effective slip-weakening distance after a reslide, as slip gradually re-localized. If this explanation is correct, the relatively small increase in  $D_c$  that we observe could be due to the lack of obvious localization in our simulations.

In our SHS simulations, we have also investigated whether changing the re-sliding velocity 589 changes either the peak friction or the approach to the future steady-state friction. Any behavior that 590 deviates from the RSF prediction is relevant to models of earthquake nucleation, as the perimeter of 591 an expanding nucleation zone subjects regions that have not slipped for a long time (as in a hold) to 592 successively larger velocity jumps (Ampuero & Rubin, 2008). For this purpose, we have run reslide 593 simulations after a hold time  $\bar{t}_{hold} \sim 1650$ , with the initial sliding velocity  $V_i = 0.02$  m/s and reslide 594 velocities  $V_r$  of 0.02, 0.05, 0.1, and 0.3 m/s. In a sense these are velocity-step tests, but run from 595 a single value of state that is much larger than the steady-state value at velocity  $V_i$ . The results are 596 shown in supplementary Fig. S2a, where friction is plotted relative to its future steady-state value. 597 The prediction of equation (1), assuming that the change in state between the end of the hold and 598 peak stress is either small or independent of the reslide velocity, is that the difference in  $\Delta \mu_{peak}$ 599 between two reslide velocities  $V_2$  and  $V_1$  is equal to  $b \ln(V_2/V_1)$ . The inset in Fig. S2-a shows that 600

this is very nearly the case, with  $\Delta \mu_{peak}$  increasing linearly with  $\ln(V_r/V_i)$  with a slope of 0.0155, 601 or 87% of the value b = 0.0178 measured in velocity-steps. Furthermore, scaling the  $\Delta \mu$  curves by 602 the value  $[C + \ln(V_r/V_i)]$  in Fig. S2-b, with the value of C = 5 determined empirically (the value of 603  $\Delta \mu_{peak}/b$  determined for  $V_r = V_i$ ), collapses the frictional response for all the reslide velocities onto 604 a single curve, consistent with the Slip law prediction. In other words, within the range of velocities 605 that we have explored, changing the reslide velocity does not affect the weakening distance  $D_c$  in the 606 granular model, consistent with the Slip law prediction, and changes the peak friction in accordance 607 with standard RSF. 608

#### **5** Energetics of granular slide-holds

Although the exact definition of an effective thermodynamic temperature for granular materials 610 is still a matter of much debate (Ono et al., 2002; Blumenfeld & Edwards, 2009; Puckett & Daniels, 611 2013; Bi et al., 2015; D. Richard et al., 2021), recent research results suggest that the fluctuating kinetic energy in these systems can play a role similar to the effective temperature. For this rea-613 son, the fluctuating kinetic energy in granular systems (that is, the kinetic energy determined after 614 subtracting from the velocity vector of each grain the average velocity vector of all the grains in its 615 immediate environment) is often referred to as the "granular temperature", and it has proven to be an 616 important control on the rheological behavior of these systems (Campbell, 1990; Losert et al., 2000; 617 Kim & Kamrin, 2020). In our previous work, we found that the magnitude of the RSF direct effect 618 parameter a in the sheared granular gouge could plausibly be explained as the ratio of the fluctuating 619 kinetic energy to the stored potential energy in the system (Ferdowsi & Rubin, 2020), although this 620 proposal requires further investigation. We further showed that in the quasi-static shearing regime 621  $(V \leq 1 \text{ m/s}, \text{ for a normal stress of 5 MPa})$ , the fluctuating kinetic energy becomes nearly constant, 622 which would suggest a nearly constant magnitude of the direct effect, consistent with most laboratory rock and gouge friction experiments (Kilgore et al., 1993; Bhattacharya et al., 2015). A nearly 624 constant value of effective granular temperature in the quasi-static regime has also been previously 625 reported in experimental granular physics studies (Song et al., 2005; Corwin et al., 2005), although 626 more recent studies of granular systems with different loading geometries (i.e., other than tabular 627 gouge layers between parallel plates) shows that this behavior could be influenced by localized de-628 formation close to driving boundaries (Gaume et al., 2020; Kim & Kamrin, 2020; P. Richard et al., 629 2020). 630

In this work, we further examine the evolution of fluctuating kinetic energy in granular slidehold simulations. The instantaneous per-grain fluctuating kinetic energy is defined in the tensorial form,

$$\delta E_{k}(t) = \frac{1}{N} \sum_{i=1}^{N} \delta \vec{v}_{i}(t) \otimes \delta \vec{v}_{i}(t), \qquad (6)$$

where  $\delta \vec{v}_i(t) = \vec{v}_i(t) - \vec{v}_i(z_k, t)$ . In these calculations,  $\vec{v}_i(z_k, t)$  is the instantaneous linear velocity field, calculated with coarse-graining of the granular model data, according to  $\vec{v}_i(z_k, t) = (1/N_k) \sum_{i=1}^{N_k} \vec{v}_i(t)$ , in which  $v_i(t)$  is the linear velocity of the *i*th particle within the rectangular cuboid with dimensions  $(L_x, L_y, \Delta z = 1.37D_{mean})$ , and  $N_k$  is the total number of grains within each cuboid.

The variation of per grain fluctuating energy  $\delta E_k$  with hold time for slide-holds with initial 635 sliding velocities  $V_i = 0.1$  and 0.02 m/s and three different system stiffnesses are shown in Figs. 7a 636 and 7b, respectively. The curves appear somewhat noisy because the individual data points are 637 snapshots and not averages over some time window. The results show that with these two initial 638 velocities, for moderate hold times  $\delta E_k$  decreases log-linearly over about 4 orders of magnitude in 639 hold time, and then plateaus at roughly 50% of its initial steady-state value. Decreasing the system 640 stiffness delays the onset of the reduction in  $\delta E_k$ , presumably because this allows stresses and sliding 641 velocities near the prior steady state to persist for longer times, but does not otherwise change the 642 shape of the energy reduction curves. This is shown by Fig. 7c, where for both  $V_i$  we further multiply the normalized hold time  $\bar{t}_{hold}$  by  $\bar{k}_d^{2/3}$ , resulting in the collapse of all the simulation results for each initial velocity (at this point the choice of 2/3 for the power is strictly empirical). Plotting the change 643 644 645

**Figure 7.** The variation of per grain fluctuating kinetic energy ( $\delta E_k$ ) with hold time in slide-hold simulations performed with three system stiffnesses  $\bar{k}_d \approx 425$ , 12, and 0.4, at two sliding velocities of (a)  $V_i = 0.1$  m/s and (b)  $V_i = 0.02$  m/s. (c) The variation of  $\delta E_k$  with (hold time)× (system stiffness,  $\bar{k}_d)^{\frac{2}{3}}$  for all data shown in panels (a) and (b). (d) same as panel (c) with  $\delta E_k$  referenced to its initial value ( $\delta E_{k,0}$ ) for each simulation. The green lines in panels (c) and (d) show the variation of  $\delta E_k$  and  $\delta E_k - \delta E_{k,0}$  for simulations with sliding velocity  $V_i = 2 \times 10^{-4}$  m/s and stiffness  $\bar{k}_d \approx 425$ . All simulations are performed at 5 MPa confining stress.

<sup>646</sup> in  $\delta E_k$  from its initial steady state value further shows that the onset of the kinetic energy reduction <sup>647</sup> is similar for both values of  $V_i$  (Figure 7d).

Figure 7c also shows that although the curves for the lower  $V_i$  have a slightly smaller  $\delta E_k$  at 648 steady state ( $\delta E_{k,ss}$ ), for all stiffnesses both  $V_i$  appear to plateau to the same value of  $\delta E_k$  at large 649 hold times. This raises the question of whether there would be any reduction in  $\delta E_k$  during the hold 650 for values of  $V_i$  small enough for  $\delta E_{k,ss}$  to be at or below this plateau value. Ferdowsi and Rubin 651 (2020) found that the steady-state value of  $\delta E_k$  decreased from about  $1.7 \times 10^{-5}$  J at  $V = 10^{-1}$  m/s 652 to slightly below  $10^{-5}$  J at  $V = 10^{-4}$  m/s (triangles in Figure 8b), close to the plateau value of  $\delta E_k$ 653 in Figure 7c. For this reason we ran slide-hold simulations with  $V = 2 \times 10^{-4}$  m/s, about the lowest 654 value that could reach moderate values of  $\bar{t}_{hold}$  in a reasonable amount of computation time (about 1.5 months). For the same reason the simulations were run only at the largest stiffness; this leads 656 to the largest reduction in  $\delta E_k$  for a given  $\bar{t}_{hold}$ . We find that, indeed,  $\delta E_k$  for these simulations 657 starts near the plateau value for the larger  $V_i$  in Figure 7c, and undergoes very little decay during the 658 hold. Despite this, the stress decay, when plotted vs. dimensionless hold time, appears very similar to that for  $V_i = 2 \times 10^{-2}$  and  $10^{-1}$  m/s (supplementary Fig. S1). This result raises the possibility that the value of  $0.8 \times 10^{-5}$  J for  $\delta E_k$  represents something of a floor for this granular system, as 659 660 661 long as stresses are large enough to drive inelastic deformation. Because of the long computation 662 times required we have been unable to explore this under conditions of steady-state sliding, but for 663 the largest-stiffness holds in Figure 7, the velocities at the end of the simulations were  $\sim 10^{-8} - 10^{-7}$ 664 m/s for the different  $V_i$  (Fig. 8a). The variation of per grain fluctuation energy versus sliding velocity 665

during holds follows closely the trend we have observed in the steady-state simulations, although it extends that trend to much lower velocities (Fig. 8b), and this suggests the sliding velocity is likely a primary factor in controlling the fluctuating energy, whether or not the system is at quasi-steady state.

**Figure 8.** (a) Estimated sliding velocities during the slide-hold simulations with  $\bar{k} \approx 425$  and initial sliding velocities  $V_i = 0.02$  m/s and 0.1 m/s in Figure 2a (solid lines), and the times at which measurements of the per grain fluctuating kinetic energy ( $\delta E_k$ ) were made (open circles), as functions of dimensionless hold time. Determining the slip speed directly from the simulations by taking the time-derivative of equation (4) (with  $\delta_{lp} = 0$ ) results in very noisy velocity histories. Instead, we estimate the slip speed from the Slip law fit to these data. These estimated velocities equal the actual velocities whenever the simulations and the Slip law fit (solid red line in Figure 2a) have the same slope at the same value of  $t_{hold}$ . (b) The variation of per grain fluctuating kinetic energy with sliding velocity in the slide-hold simulations of panel (a) (magenta and brown circles) and in steady-state simulations reported in Ferdowsi and Rubin (2020) (blue triangles; the break in slope just below 1 m/s marks the boundary between the quasi-static and inertial regimes of flow). All simulations are performed at 5 MPa confining stress.

We do not yet understand what controls the nearly fixed value of the fluctuating kinetic energy 670 at long hold times or low steady-state sliding speeds in our simulations. For as long as  $\delta E_k$  is nearly 671 constant, the energy loss from grain-grain friction and inelastic collisions must be balanced by work 672 done on the gouge by the moving upper plate (or a reduction in elastic potential energy, but this is not 673 an option during steady sliding, and even during holds, at constant confining pressure this strikes us 674 as a less likely source). During load-point holds this work comes from both shearing (equivalent to 675 the potential energy loss of the attached spring) and compaction. In these high-stiffness simulations 676 the shearing and compaction velocities are of the same order of magnitude. As both decay roughly 677 logarithmically with time during the hold, the rate of energy loss must also decay logarithmically 678 with time. For our default restitution coefficient  $\epsilon$  of ~0.98, collisions are nearly perfectly elastic 679 and we presume that most of the energy loss is due to grain-grain friction. To explore the effect of 680 increasing the collisional energy loss, we ran simulations with  $\epsilon \sim 0.3$ , for  $\bar{k}_d \approx 12$ . The results 681 of these highly damped simulations are shown in Fig. 9. We find that the stress decay is nearly 682 indistinguishable from that with the higher restitution coefficient (Figure 9a), and that while  $\delta E_k$  for 683 the lower restitution coefficient is offset to lower values, the shape of the curve of fluctuating energy 684 with hold time is not much different (Figure 9b). We conclude that within the range explored, the 685 choice of restitution coefficient does not significantly influence the mechanical behavior of these 686 systems at such low strain rates, consistent with previous results (MiDi, 2004; Ferdowsi & Rubin, 687 2020). 688

If, as was proposed by Ferdowsi and Rubin (2020), the RSF direct effect parameter *a* is proportional to  $\delta E_k$ , then Figure 7 suggests that *a* might vary by a factor of ~2 over the duration of

**Figure 9.** (a) The variation of friction coefficient, normalized by the RSF parameter *b*, as a function of normalized hold time, for granular slide-hold simulations with sliding velocity  $10^{-1}$  m/s and two restitution coefficients of  $\epsilon \sim 0.98$  and  $\epsilon \sim 0.3$ . (b) The variation of fluctuating kinetic energy with normalized hold time for the simulations in panel (a). The shaded regions indicate  $2-\sigma$  standard deviations of 8 different realizations. The gray curve shows the fluctuating kinetic energy for the simulation with  $\epsilon \sim 0.98$  shifted vertically.

the holds with the larger  $V_i$ . One could then ask if the generally good fit of the Slip law, using 691 constant parameter values, to the decay of friction during these same holds and to laboratory data, 692 as in Figure 2, is really supportive of the Slip law for state evolution (that is, supportive of a model 693 in which healing does not occur in the absence of slip). For example, is it possible that the friction 694 data could be well fit by the Aging law (that is, by a model in which healing occurs with time even 695 in the absence of slip), given the proper velocity-dependence of a? However, we note that for the 696 highest-stiffness simulations in Figures 2 and 7, the continual log-linear stress decay continues to be 697 well fit by the Slip law with constant parameter values even for dimensionless hold times larger than 698 ~10<sup>0.5</sup>, where  $\delta E_k$  is essentially constant. In addition, for the simulation with  $V_i = 2 \times 10^{-4}$  m/s in 699 supplementary Figure S1,  $\delta E_k$  is roughly constant and  $t_{hold}$  is arguably large enough to show that 700 the friction data are more consistent with slip-dependent rather than time-dependent healing. We 701 leave further investigation of the potential relation between measures of effective temperature and 702 the value of a in granular simulations for future work. 703

#### 704 6 Conclusions

In this work, we investigated the behavior of a sheared granular layer subjected to loading 705 conditions designed to mimic laboratory slide-hold-slide experiments, for a range of sliding veloc-706 ities and system stiffnesses We compared the transient frictional behavior of the model to existing 707 rock friction data, as well as to the predictions of standard rate-state friction (RSF) constitutive 708 equations. For the past few decades it has been common in the rock deformation and earthquake 709 physics communities to interpret the direct rate dependence of RSF as resulting from a thermally-710 activated process involving the breaking of chemical bonds at contacting asperities, and to interpret 711 state evolution as due to time-dependent plasticity (or perhaps time-dependent bond strengthening) 712 at those asperities. We have removed this basic ingredient from our simulations, and instead ex-713 plored whether transient friction as observed in the laboratory could arise simply from momentum 714 transfer in a granular layer with constant friction at grain/grain contacts. Such a granular layer might 715 represent a natural fault gouge, or, in the laboratory context, a synthetic gouge layer, a powder that 716 arises during slip on initially bare rock surfaces, or, owing to similarities in behavior between gran-717 ular systems and disordered solids (Manning & Liu, 2011; Cubuk et al., 2017), perhaps amorphous 718 719 wear products on those surfaces. Simulated velocity steps in the same granular model have already shown a direct velocity-dependence and an opposing state evolution-dependence of friction, each 720 proportional to the logarithm of the velocity jump, with magnitudes (the RSF parameters a and b) of 721

~0.02, not far from lab values. In addition, state evolution following the velocity jumps occurs over
 a slip distance that is independent of the size and sign of the velocity step, consistent with laboratory
 experiments and the Slip law for state evolution. A final motivation for our simulations is that while
 the RSF equations are largely empirical, the granular model is physics-based, and its output allows
 us to investigate and perhaps understand why it behaves as it does.

The behavior of the granular flow model in slide-hold simulations appears to closely resem-727 ble laboratory experiments in two important respects. First, the continual stress decay during the 728 hold is reasonably well modeled by the Slip version of the RSF equations, using parameter values 729 determined independently from velocity step tests on the identical system. This is consistent with 730 lab data, as is the result that for both the granular simulations and lab data, the Aging version of 731 the RSF equations predicts too little stress decay. This is because it predicts too much healing, i.e. 732 state evolution, which for the Aging law progresses with time rather than slip (Bhattacharya et al., 733 2017, 2021). Under standard RSF, with no intrinsic velocity scale, the stress decay as a function 734 of normalized hold time  $t_{hold}/(D_c/V_i)$  must be independent of the initial sliding velocity  $V_i$ . This 735 is approximately the case for our stiffest simulations ( $k \sim 425$ ), but larger differences arise for the 736 stiffnesses more appropriate for lab experiments ( $\bar{k} \sim 12$  and 0.4), where the prediction of the Slip 737 law falls roughly between the simulation results. There is not much lab data investigating this ques-738 tion. The experiments of (Marone & Saffer, 2015) on simulated gouge show a modest dependence 739 on  $V_i$ , when plotted vs. normalized hold time, but the sign of that dependence seems to be opposite 740 from our granular simulations. The experiments of Carpenter et al. (2016), however, do not show 741 this dependence. The source of the  $V_i$ -dependence in the granular simulations, and whether it might 742 be related to the variation of  $\delta E_k$  for  $10^{-4} \leq V \leq 10^{-1}$  m/s in Figure 8b, is unknown. 743

Second, in both the granular simulations and laboratory experiments, the fault layer undergoes 744 745 compaction roughly linearly with log time. Even the rates are roughly comparable, at ~  $0.05D_c$ per decade of hold time in Figure 4. Log-time compaction is consistent with standard interpreta-746 tions of the time-dependent Aging law for state evolution (compaction being a proxy for growth 747 of true contact area), even though in both the granular simulations and lab experiments the stress 748 decay is consistent with the Slip law and not the Aging law. As with the large velocity-step de-749 creases described by Ferdowsi and Rubin (2020), this suggests a decoupling between state evolution 750 and changes in fault or gouge thickness, in both the lab and the granular simulations, that seems 751 inconsistent with traditional interpretations of RSF (Sleep, 2006, e.g.). 752

The reslide portions of our granular slide-hold-slide simulations share with laboratory experi-753 ments the result that, for sufficiently long holds, the peak friction upon resliding ("frictional healing", 754  $\Delta \mu_{peak}$ ) increases nearly linearly with the logarithm of hold time (J. H. Dieterich, 1972; Marone et 755 al., 1990). For our maximum stiffness and larger lab-like stiffness ( $\bar{k} \approx 12$ ), the long-time healing 756 rate  $d\Delta \mu_{peak}/d\ln(\bar{t}_{hold})$  is very close to the RSF evolution-effect parameter b, as predicted by the 757 Aging law for all stiffnesses, but for our smaller lab-like stiffness ( $k \approx 0.4$ ) it is only half that value. 758 The range of slopes we find is close to the range  $\sim 0.3 - 0.7b$  seen in a study where the value of 759 b was determined independently from velocity-step tests (Ikari et al., 2016; Carpenter et al., 2016). 760 However, unlike the lab data of Beeler et al. (1994), we find this slope to be dependent upon the 761 stiffness of the testing apparatus, by a factor of 2. System stiffness is potentially important because 762 it controls the amount of interfacial slip during the load-point hold; for our longest hold durations 763 this slip is  $\sim D_c$  for our larger lab-like stiffness, and  $\sim 10D_c$  for our smaller. However, the effect of 764 stiffness on healing rates in our simulations and in lab data seems to be at most rather modest. 765

There also appears to be no influence of the initial sliding velocity  $V_i$  on the rate of frictional healing at long hold times in our SHS simulations. In this respect they are similar to the laboratory experiments of Carpenter et al. (2016), but not Marone and Saffer (2015), both conducted in the range  $V_i = 1 - 100 \ \mu$ m/s, somewhat below to far below the velocities we could achieve.

To summarize, the granular model mimics laboratory slide-hold experiments in that the stress decay during the hold is well approximated by the Slip law for state evolution, using parameter values determined from velocity steps on the same sample. In addition, both the granular simulations and laboratory experiments undergo roughly log-time compaction at comparable rates, when those

rates are normalized by the appropriate value of  $D_c$ . For slide-hold-slide protocols, the granular 774 model mimics laboratory experiments in that the rate of healing at sufficiently long hold times is 775 roughly linear with log time, with a slope that is near to that observed in the lab (a modest fraction 776 of b). Thus, despite several shortcomings, including the use of spherical grains with a geologi-777 cally narrow size distribution, and a range of sliding velocities that, due to computational expense, 778 are very high by lab standards, it can still be argued that the granular model does a better job of 779 matching laboratory experiments than existing, and empirical, rate-state friction equations. Unlike 780 the comparison of velocity-step simulations to lab experiments emphasized by Ferdowsi and Rubin 781 (2020), for the SHS protocols there are clearly some failures as well as successes of the granular 782 model. It is entirely possible that some of these failures are due to time-dependent contact-scale 783 processes in lab experiments that we specifically excluded from our simulations. 784

Researchers in the fields of granular physics and granular rheology have previously found that 785 the fluctuating kinetic energy,  $\delta E_k$ , sometimes referred to as the "granular temperature", in part 786 controls the rheology of these materials in steady-state and some transient regimes (Kim & Kamrin, 787 2020; Gaume et al., 2020; Campbell, 1990). In our previous study, we found that although  $\delta E_k$ 788 varied with confining pressure, the ratio of  $\delta E_k$  to elastic strain energy within the gouge varied only 789 slightly with pressure and steady-state sliding speed, and was close to the (also nearly constant) value 790 of the the direct velocity effect parameter a of the granular layer (Ferdowsi & Rubin, 2020). In that 791 paper we evaluated the variation in fluctuating kinetic energy at steady-state shear velocities as low 792 as  $10^{-4}$  m/s. In the slide-hold simulations reported here, we find that  $\delta E_k$  becomes even more nearly constant down to transient sliding velocities below  $10^{-7}$  m/s. We also find here that changing the 794 damping (energy loss) for grain-grain interactions does not substantially alter the variation of  $\delta E_k$ , 795 or the stress decay during holds, for the range of parameters explored. Further understanding what 796 controls the changes in fluctuating kinetic energy, its near-constant value in the quasi-static limit, and its relation to the direct effect parameter a, may guide future studies of the proper formulations 798 of rate-and-state friction laws for describing the transient frictional response of granular layers, and 799 for connecting the RSF framework to more physics-based models. 800

Additional future research may explore recent definitions of state variable for amorphous ma-801 terials (e.g., D. Richard et al. (2021)) in the context of elastoviscoplastic rheology for soft glassy 802 materials (e.g., Fielding (2020)). These works may also address the applications of some of the 803 latest developments in constitutive modeling of complex fluids with potentially similar (but as-yet 804 unexplored in the context of rock and sediment friction) rate-dependent rheological response and 805 hysteresis to rate- and state-dependent behavior of Earth materials. Also, our study here has been 806 focused on the stress relaxation and healing behavior of a sheared granular layer that shows velocity-807 strengthening frictional behavior. It has been recently observed that, even without implementing 808 any sophisticated or time-dependent grain-contact scale processes in granular simulations, granular 809 models that use certain grain shapes (Salerno et al., 2018), or grain-grain contact potentials/laws in 810 certain regions of normal pressure and grain stiffness (such as the Hookean contact law, in the grain 811 strain range smaller than 10<sup>-3</sup> (Kim & Kamrin, 2020; DeGiuli & Wyart, 2017)) show velocity-812 weakening friction in the dense quasi-static flow regime. Exploring the transient rheology of such 813 velocity-weakening systems in velocity-step and slide-hold-slide protocols, may provide more insights into the physics of granular rate-state behavior, and additional opportunities for comparing 815 the behavior of the granular model to lab data when both are in the velocity-weakening regime of 816 friction. 817

#### 818 Acknowledgments

BF acknowledges support from the Department of Geosciences, Princeton University, in form of a Harry H. Hess postdoctoral fellowship. Research was sponsored by the US National Science Foundation (NSF) awards EAR-1547286 and EAR-1946434, by the US Geological Survey (USGS), Department of the Interior, awards G19AP00048 and G20AP00112, and by the US Army Research Office (ARO) award W911NF-20-1-0154, all of the awards to AMR. The authors thank Pathikrit Bhattacharya, Terry E. Tullis, Nicholas M. Beeler, and Keishi Okazaki, for their permission to use the data shown in Figure 2d of this manuscript. Parallel programs were run on computers provided

by the Princeton Institute for Computational Science and Engineering (PICSciE). The 3-D visual-826 izations of the model were performed using the open-source visualization software "The Persistence 827 of Vision Raytracer" POV-Ray (http://www.povray.org). Most of the data analysis were carried out 828 using the open-source Python library, NumPy (https://numpy.org). The 2-D plots were made with 829 the Python library Matplotlib (www.matplotlib.org). The computer codes for LAMMPS simula-830 tions of this paper with the information about the version of LAMMPS used for the simulations, 831 are available on the Dryad digital repository at https://doi.org/10.5061/dryad.2z34tmphk. ### 1. Background of the Discrete Element Method (DEM) used in this study

For two spheres  $\{i, j\}$  in contact with each other that have the positions  $\{r_i, r_j\}$ , and diameters  $d_i$  and  $d_j$ , the normal  $(F_{n_{ij}})$  and tangential  $(F_{t_{ij}})$  forces on particle *i* in its interaction with particle *j* can be calculated from the following equations:

$$\boldsymbol{F}_{n_{ij}} = \sqrt{\delta_{ij}} \sqrt{\frac{d_i d_j}{2(d_i + d_j)}} (k_n \delta_{ij} \boldsymbol{n}_{ij} - m_{eff} \gamma_n \boldsymbol{v}_{n_{ij}})$$
(1)

$$\boldsymbol{F}_{t_{ij}} = \sqrt{\delta}_{ij} \sqrt{\frac{d_i d_j}{2(d_i + d_j)}} (-k_t \boldsymbol{u}_{t_{ij}} - m_{eff} \gamma_t \boldsymbol{v}_{t_{ij}})$$
(2)

in which  $k_n$  and  $k_t$  are the normal and tangential stiffness, and are defined as  $k_n = (2/3)E/(1-\nu^2)$ and  $k_t = 2E/(1+\nu)(2-\nu)$  (Mindlin, 1949). In the relations for the normal and tangential stiffnesses, E and  $\nu$  are the Young's modulus and Poisson's ratio, respectively, and  $m_{eff} = m_i m_j/(m_i + m_j)$  is defined as the effective mass of the two interacting spheres that have masses  $m_i$  and  $m_j$ . The relative normal and tangential velocities,  $\boldsymbol{v}_{n_{ij}}$  and  $\boldsymbol{v}_{t_{ij}}$ , of the grains used in Eqs. 1 and 2 are defined as:

$$\boldsymbol{v}_{n_{ij}} = (\boldsymbol{v}_{ij} \cdot \boldsymbol{n}_{ij}) \boldsymbol{n}_{ij} \tag{3}$$

$$\boldsymbol{v}_{t_{ij}} = \boldsymbol{v}_{ij} - \boldsymbol{v}_{n_{ij}} - \frac{1}{2}(\boldsymbol{\omega}_i + \boldsymbol{\omega}_j) \times \boldsymbol{r}_{ij}$$
(4)

in which  $\{\boldsymbol{v}_i, \boldsymbol{v}_j\}$  are the linear, and  $\{\boldsymbol{\omega}_i, \boldsymbol{\omega}_j\}$  are angular components of grain velocities, and  $\boldsymbol{r}_{ij} = \boldsymbol{r}_i - \boldsymbol{r}_j$ ,  $\boldsymbol{n}_{ij} = \boldsymbol{r}_{ij}/r_{ij}$ , with  $r_{ij} = |\boldsymbol{r}_{ij}|$ , and  $\boldsymbol{v}_{ij} = \boldsymbol{v}_i - \boldsymbol{v}_j$ . Additionally,  $\delta_{ij}$  is the normal compression of the grain and is defined as

$$\delta_{ij} = \frac{1}{2}(d_i + d_j) - r_{ij} \tag{5}$$

In Eqs. 1 and 2, the parameters  $\gamma_n$  and  $\gamma_t$  are the normal and tangential damping (viscoelastic) constants of the grain-grain interaction, respectively; For the choices of these two damping constants, we use the default LAMMPS option where  $\gamma_t = 0.5\gamma_n$  (it has been shown that the choices of the ratio have little impact on the rheology of granular materials in the dense and quasi-static regime of shearing of hard particles we explore in this work (Ferdowsi & Rubin, 2020; Gaume et al., 2011; da Cruz et al., 2005; Silbert et al., 2001)). In the granular module of LAMMPS, the damping is implemented as a spring and dashpot in parallel for both the normal and tangential contacts.

Having defined the equations for contact forces and torques on each particle, i, we solve the Newton's second law to find the translational and rotational accelerations of particles located in a gravitational field  $\boldsymbol{g}$ ,

$$\boldsymbol{F}_{i}^{tot} = m_{i}\boldsymbol{g} + \sum_{j} \left( \boldsymbol{F}_{n_{ij}} + \boldsymbol{F}_{t_{ij}} \right)$$
(6)

$$\boldsymbol{\tau}_{i}^{tot} = -\frac{1}{2} \sum_{j} \boldsymbol{F}_{t_{ij}} \times \boldsymbol{r}_{ij}$$

$$\tag{7}$$

Slip occurs at grain contacts when the local shear stress exceeds the specified (constant) local grain-grain friction coefficient,  $\mu_g$ . The value of  $\mu_g$  determines the upper limit of the tangential force between two grains from the Coulomb criterion  $F_t \leq \mu_g F_n$ . This tangential force grows according to the non-linear Hertz-Mindlin contact law up to the point where  $F_t/F_n = \mu_g$ . After this point, the tangential force is held at  $F_t = \mu_g F_n$  until the point that due to rearrangement of grains either  $F_t \leq \mu_g F_n$  or the contact between grains is lost. While the model solves the

Newton's second law for each particle, it does not take into account wave propagation inside the grains.

Energy loss at contacts in the granular model is characterized by the "restitution coefficient", which potentially varies from 0 (complete energy loss) to 1 (zero loss). At the low sliding speeds of interest the adopted value of "restitution coefficient" appears to have very little influence on the macroscopic behavior of the system (Gaume et al., 2011; da Cruz et al., 2005; Silbert et al., 2001). The values of restitution coefficients,  $\epsilon_n$  and  $\epsilon_t$  for the normal and tangential directions respectively, are controlled by the choices of the damping coefficients  $\gamma_{n,t}$  and contact stiffness  $k_{n,t}$ . For Hertzian contact law at the grain-grain scale, the restitution coefficient in the normal direction is obtained from the equation of relative motion of two spheres in contact:

$$\ddot{\delta} + \frac{E\sqrt{2d_{eff}}}{3m_{eff}(1-\nu^2)} \left(\delta^{3/2} + \frac{3}{2}A\sqrt{\delta}\dot{\delta}\right) = 0$$
(8)

with the the initial condition  $\dot{\delta}(0) = \mathbf{v}_n$  and  $\delta(0) = 0$ . Further, the variable A is defined as  $A = \frac{1}{3} \frac{(3\gamma_t - \gamma_n)^2}{(3\gamma_t + 2\gamma_n)} \left(\frac{(1-\nu^2)(1-2\nu)}{E\nu^2}\right)$ , and  $d_{eff} = d_i d_j / (d_i + d_j)$  is the effective diameter for spheres of diameters  $d_i$  and  $d_j$ . From solving this equation, the normal component of the coefficient of restitution is defined as the ratio of normal velocity of grains at the end of the collision, defined as  $\dot{\delta}(t_{col})$ , to the initial normal impact velocity of the grains:  $\epsilon_n = \dot{\delta}(t_{col})/\dot{\delta}(0)$ . Solving the same equation also gives the collision time  $t_{col}$  for given choices of the physical properties of grains and initial velocities that two grains collide. The restitution coefficient in the tangential direction can be obtained from a similar procedure but with implementing tangential damping coefficient (Brilliantov et al., 1996). The time step of our simulations is defined as  $\Delta t = t_{col}/100$ , with  $t_{col}$  evaluated here with the assumption of an impact velocity  $\dot{\delta}(0)$  of 25 m/s (to be on the safe side for the choice of the simulation time-step and solve the equations of motions accurately; grain-grain impact velocities are highly unlikely to achieve 25 m/s at a given time-step in the quasi-static

FERDOWSI & RUBIN: FRICTIONAL HEALING IN A SIMULATED GRANULAR FAULT GOUGE X - 5 simulations reported in this work). The time-step criteria  $\Delta t = t_{col}/50$  is based on previous values used and recommended by Silbert et al. (2001). The majority of the simulations in this study were performed with a very high restitution coefficient of  $\epsilon_n = 0.98$ , such that the system is damped minimally. However, we also have run a series of slide-hold simulations with a much lower restitution coefficient of  $\epsilon_n = 0.3$ . It can be argued that damping introduces some timedependence at the contact scale. However, we have previously tested the transient behavior of the model considered here using the restitution coefficients that varied from nearly zero (complete damping) to nearly 1 (no damping) and found that the choice of the restitution coefficient exerted no significant influence on the system's behavior in the slow-sliding regime that we have been interested in exploring here and in the previous work (Ferdowsi & Rubin, 2020). With the very high choice of the restitution coefficient ( $\epsilon_n = 0.98$ ), we refer to the model as practically having no time-dependence at the contact scale. Further information about the granular module of LAMMPS can be found in the LAMMPS manual and several references (Zhang & Makse, 2005; Silbert et al., 2001; Brilliantov et al., 1996). For more details about the implementation of the model in this manuscript, and a complete list of the governing dimensionless variables, we refer the reader to the "Computational Model" section and Appendix A of Ferdowsi and Rubin (2020). All details of the present model, except for the values of pulling spring stiffness or unless otherwise specified in the following, are identical to the "default" model of our previous paper.

It can be argued that damping introduces some time-dependence at the contact scale. However, we have previously tested the transient behavior of the model considered here using the restitution coefficients that varied from nearly zero (complete damping) to nearly 1 (no damping) and found that the choice of the restitution coefficient exerted no significant influence on the system's behavior in the slow-sliding regime that we have been interested in exploring here and in the

previous work (Ferdowsi & Rubin, 2020). With the very high choice of the restitution coefficient  $(\epsilon_n = 0.98)$ , we refer to the model as practically having no time-dependence at the contact scale.

Table S1. DEM simulation parameters. If in some limited simulations, different parameter values are used, they are explicitly mentioned in the text.

Parameter	Value
Grain density, $\rho$	$2500~[\mathrm{kg/m^3}]$
Young's modulus, $E$	$50 \; [\text{GPa}]$
Poisson ratio, $\nu$	0.3
Grain-grain friction coefficient, $\mu_g$	0.5
Confining pressure, $\sigma_n$	5
Coefficient of restitution, $\epsilon_n$	0.98
Time step, $\Delta t$	$2 \times 10^{-8}  [s]$

Figure S1. The variation of friction coefficient in slide-hold simulations with prior sliding velocities  $V_i$  of  $2 \times 10^{-4}$ ,  $2 \times 10^{-3}$ ,  $2 \times 10^{-2}$ , and  $10^{-1}$  m/s. All simulations are run with system stiffness  $\bar{k}_d \approx 425$  at the confining stress 5 MPa. The lines show the mean behavior of 8 realizations for each system, and the width of the shades regions around each line shows the 2-sigma deviations. The pink and green lines in panels (a) & (b) further show the predictions of the Slip and Aging laws, respectively, using the RSF parameters ( $D_c = 0.0053$  m, a = 0.0247, b = 0.0178) determined independently from Slip-law fits to velocity-step tests performed on the same model (Ferdowsi and Rubin, 2020).
