Abstract

The pre-industrial (Year 1850) to present-day (Year 2014) increase in methane from 808 to 1831 ppb leads to an effective radiative forcing (ERF) of 0.97 ± 0.04 Wm⁻² in the United Kingdom's Earth System Model, UKESM1. The direct methane contribution is 0.54+-0.04 Wm⁻². It is better represented in UKESM1 than in its predecessor due to the inclusion of shortwave absorption, updates to the longwave spectral properties, and no interference from dust. An indirect ozone ERF of 0.13-0.20 Wm⁻² is largely due to the radiative effect of the tropospheric ozone increase outweighing that of the stratospheric ozone decrease. An indirect water vapor ERF of 0.07+-0.05/0.02+-0.04 Wm⁻² is consistent with previous estimates based on the stratospherically-adjusted radiative forcing metric. The methane increase also leads to a cloud radiative effect of 0.12+-0.02 Wm⁻² from aerosol-cloud interactions and thermodynamic adjustments. The aerosol-mediated contribution (0.28-0.30 Wm⁻²) arises because methane-driven oxidant changes alter the rate of new particle formation (-8 %), causing a change in the aerosol size distribution towards fewer larger particles. There is a resulting decrease in cloud droplet number concentration and an increase in cloud droplet effective radius. There are additional shortwave and longwave contributions of 0.23 and -0.35 Wm⁻² to the cloud forcing which are dynamically-driven. They arise from radiative heating and stabilization of the upper troposphere, resulting in a reduction in global cloud cover and convection. These results highlight the importance of chemistry-aerosol-cloud interactions and dynamical adjustments in climate forcing and can explain some of the diversity in multi-model estimates of methane forcing.

Key Points:

• The direct radiative effect of methane in UKESM1 is consistent with line-by-line radiative transfer calculations

- The total methane effective radiative forcing in UKESM1 includes an aerosol-mediated cloud forcing due to changes in cloud activation.
- The effective radiative forcing also includes a dynamically-driven cloud forcing from tropospheric warming and a reduction in cloud fraction.
- ٠

Abstract

The pre-industrial (Year 1850) to present-day (Year 2014) increase in methane from 808 to 1831 ppb leads to a global mean effective radiative forcing (ERF) of 0.97 ± 0.04 W m⁻² in the United Kingdom's Earth System Model, UKESM1. The direct methane contribution is 0.54 + 0.04 W m⁻². It is better represented in UKESM1 than in its predecessor model HadGEM2 due to (i) the inclusion of absorption in the shortwave, (ii) updates to the spectral properties in the longwave, and (iii) the absence of an anomalous dust response in the UKESM1 simulations. An indirect ozone ERF of 0.13-0.20 W m⁻² is largely due to the radiative effect of the tropospheric ozone increase outweighing that of the stratospheric ozone decrease. An indirect water vapor ERF of 0.07 + 0.05/0.02 + 0.04 W m⁻² is consistent with previous estimates based on the stratospherically-adjusted radiative forcing metric. The methane increase also leads to a cloud radiative effect of 0.12 + 0.02 W m⁻² from aerosol-cloud interactions and thermodynamic adjustments. The aerosolmediated contribution $(0.28 - 0.30 \text{ W m}^{-2})$ arises because methane-driven changes in oxidants alter the rate of new particle formation (-8%), causing a change in the aerosol size distribution towards fewer but larger particles. There is a resulting decrease in cloud droplet number concentration and an increase in cloud droplet effective radius. There are additional shortwave and longwave contributions of 0.23 and -0.35 W m⁻² to the cloud forcing which are dynamically-driven. They arise from radiative heating and stabilization of the upper troposphere, resulting in a reduction in global cloud cover and convection. These results highlight the importance of chemistry-aerosol-cloud interactions and dynamical adjustments when quantifying climate forcing and can explain some of the diversity in multi-model estimates of methane forcing.

Plain Language Summary

Methane is the second most important greenhouse gas after carbon dioxide. Methane is also chemically reactive in the atmosphere, and can cause changes in ozone, which is also a greenhouse gas. Methane can also affect the amount of water vapor in the atmosphere, where it too acts as a greenhouse gas. Aerosols, formed in the atmosphere through chemical processing, are also affected by methane. This study quantifies the impact of changes in methane concentration since the pre-industrial period on the Earth's energy budget at the present day and examines the impact from methane itself, as well as the impact from the additional methane-driven changes in ozone, water vapor, aerosols, and clouds. The biggest impact (~55 %) is from methane itself, and of the remaining impact on the Earth's energy budget from methane, less than half is from ozone and clouds. The contribution from clouds is partly driven by changes in aerosol properties and partly driven by heating and a reduction in cloud cover. The impact from water vapor is small and is consistent with previous estimates. This study highlights the importance of including chemistry-aerosol-cloud interactions when quantifying the effect of pre-industrial to present-day changes in atmospheric constituents on climate.

1 Introduction

Methane (CH₄) is the second most important greenhouse gas (GHG) after carbon dioxide (CO₂) (Myhre et al., 2013). Due to its relatively short atmospheric lifetime of 11.2 + 1.3 yr (Prather et al., 2012) and its radiative efficiency being an order of magnitude larger than for CO₂ (Ramaswamy et al., 2001; Myhre et al., 2013), CH₄ has an important role in mitigating near-term climate change (e.g., UNEP, 2011; Allen et al., 2018; Allen et al., 2021; Abernethy et al., 2021). However, future concentrations may be subject to climate feedbacks involving CH₄ natural sources (e.g., O'Connor et al., 2010; Dean et al., 2018; Gedney et al., 2019; Thornhill et al., 2021a; Kleinen et al., 2021). It is therefore important to quantify its climate forcing and relevant feedbacks for understanding the historical and future evolution of climate.

In relation to its climate forcing, CH_4 has a direct radiative effect and indirect effects due to its reactivity.

As well as being a tropospheric ozone (O_3) precursor, CH_4 affects stratospheric O_3 (Pawson et al., 2014) and together, the O_3 changes lead to an indirect contribution to the total CH_4 forcing. CH_4 oxidation is also a major sink for the hydroxyl (OH) radical, and changes in CH_4 lead to changes in O_3 , OH, and other oxidants. These oxidants determine the rate of formation of secondary aerosol such as sulfate and secondary organic aerosol (SOA) (e.g., Kelly et al., 2018; Mulcahy et al., 2020), potentially giving rise to additional indirect aerosol forcings (e.g., Shindell et al., 2009; Karset et al., 2018) through aerosol-radiation interactions (ari) and/or aerosol-cloud interactions (aci), although these effects have not been well quantified to date.

Water vapor (WV) is also an important component of the radiative balance in the stratosphere (e.g., Forster and Shine, 1999). Trends in observed stratospheric WV could be due to increases in stratospheric CH_4 oxidation (Hansen et al., 2005) or direct aircraft emissions (Wilcox et al., 2012). However, some of the observed increase can be attributed to a climate feedback (e.g., Dessler et al., 2013). Studies disagree on the relative role of CH_4 (e.g., Oman et al., 2011; Hurst et al., 2011). Nevertheless, it is clear that indirect forcings through changes in O_3 , stratospheric WV, and potentially aerosols, can significantly impact CH_4 forcing (Hansen et al., 2005; Shindell et al., 2005; Shindell et al., 2009; Myhre et al., 2013; Winterstein et al., 2019; Thornhill et al., 2021b).

Recent studies that rank anthropogenic drivers of climate change make use of the effective radiative forcing (ERF) as the preferred metric of choice (e.g., Smith et al., 2018; Smith et al., 2020; O'Connor et al., 2021; Thornhill et al., 2021b) since it is more representative of the predicted global mean temperature response (Hansen et al., 2005; Richardson et al., 2019). It was defined in the Intergovernmental Panel on Climate change (IPCC) 5th assessment report (AR5; Myhre et al., 2013) at the top-of-atmosphere (TOA) as:

$$ERF = IRF + \sum_{i=1}^{n} A_i$$

where IRF is the TOA instantaneous radiative forcing from an imposed perturbation (e.g., a change in a GHG concentration) and A_i is a rapid atmospheric or land surface adjustment (e.g., atmospheric temperature, clouds, water vapour, albedo, etc.) that gives rise to additional positive or negative changes in the net TOA radiative fluxes. The ERF differs from the more traditional radiative forcing metric, in that the latter only includes a stratospheric temperature adjustment, whereas the ERF also includes tropospheric and land surface adjustments.

In the case of the direct radiative effect of CH_4 , Smith et al. (2018) found that the present-day (PD) CH_4 ERF is approximately equivalent to its IRF. The rapid adjustment associated with stratospheric temperature is negligible and the other adjustments (e.g., tropospheric temperature and water vapor) are small, have opposing signs, and roughly sum to zero. However, as indicated above, there are additional Earth System (ES) interactions or chemical adjustments that affect the net TOA radiative fluxes when CH_4 is considered within a full ES context (e.g., Hansen et al., 2005; Shindell et al., 2005; Shindell et al., 2009; Winterstein et al., 2019). Therefore, when quantifying the climate forcing of CH_4 , ES interactions or chemical adjustments need to be fully considered (Shindell et al., 2009; Myhre et al., 2013) in addition to physical adjustments (Smith et al., 2018).

A recent study by Thornhill et al. (2021b) quantified a range of PD anthropogenic ERFs and considered both physical and chemical adjustments using an ensemble of models that participated in the Aerosol and Chemistry Model Intercomparison Project (AerChemMIP; Collins et al., 2017). The multi-model PD CH₄ ERF was 0.67 ± 0.17 W m⁻². Some of the model spread is due to differing complexities in the representation of chemistry in the respective models (and hence differences in their indirect contributions, e.g., from O₃). However, some of the model diversity is due to differences in the sign and magnitude of the cloud adjustment (-0.06 to 0.24 W m⁻²). Although other AerChemMIP models show a positive cloud adjustment (e.g., GISS-E2-1 (Bauer et al., 2020) and CESM-WACCM (Emmons et al., 2020)), the United Kingdom's Earth System Model, UKESM1 (Sellar et al., 2019), has the strongest positive cloud adjustment of the AerChemMIP models. This results in UKESM1 being one of only two models (including CESM-WACCM) to have a positive tropospheric adjustment overall and the highest PD CH₄ ERF of 0.97 +- 0.04 W m⁻² (O'Connor et al., 2021) of the multi-model ensemble.

In the Thornhill et al. (2021b) study, radiative kernels (Chung and Soden, 2015; Smith et al., 2018; Smith et al., 2020) and diagnostic radiation calls (Ghan, 2013) enabled a breakdown of the total CH_4 ERF into different constituents (gas phase versus aerosol phase). However, it is unclear whether the relevant adjustments are additive when more than one forcing agent is perturbed (as is the case for CH_4 in an ES context). The kernel approach also cannot distinguish between cloud adjustments that are dynamically driven and those that are due to changes in aerosol-mediated cloud nucleation (Thornhill et al., 2021b). As a result, a complete process-based understanding of the UKESM1 total CH_4 ERF and the AerChemMIP multi-model diversity in the PD CH_4 ERF is lacking.

The aim of the current study is thus to apportion the UKESM1 PD CH₄ forcing quantified in O'Connor et al. (2021) between the direct CH₄ contribution and indirect contributions using the widely-adopted metric of choice for forcing, i.e., ERF, thereby including physical and chemical rapid adjustments. This study will also aim to test whether the relevant contributions (including adjustments) are additive and provide a process-based understanding of the positive cloud adjustment in UKESM1. Although CH₄can affect the lifetime of other GHGs such as chlorofluorocarbons (Boucher et al., 2009) or nitrous oxide (Hsu and Prather, 2010), they are concentration-driven in UKESM1 and their response to CH₄ is therefore constrained. As a result, the focus here will be on the direct CH₄ ERF from the change in CH₄ concentration between the pre-industrial (PI) period and the PD, and the corresponding indirect ERFs from CH₄-driven changes in O₃, stratospheric WV, and potentially aerosols. The paper is organised as follows. Section 2 gives a brief description of the UK's Earth System Model (UKESM1) and the experimental design used in this study. Results can be found in Sect. 3 while conclusions can be found in Sect. 4.

2 Model Description and Experimental Design

The model used in this study is the atmospheric and land components of the UK's Earth System Model, UKESM1 (Sellar et al., 2019). It has a resolution of N96L85, equivalent to a horizontal resolution of approximately 135 km, with 85 hybrid height levels covering an altitude range from the surface up to the model lid at 85 km. The model includes a troposphere-stratosphere chemistry scheme (Archibald et al., 2020) from the United Kingdom Chemistry and Aerosol (UKCA) model (Morgenstern et al., 2009; O'Connor et al., 2014) coupled to a two-moment aerosol scheme called GLOMAP-mode (Mann et al., 2010; Mulcahy et al., 2018; Mulcahy et al., 2020). A full description and evaluation of the gas-phase chemistry and aerosol schemes in UKESM1 can be found in Archibald et al. (2020) and Mulcahy et al. (2020), respectively.

Here, UKESM1 is run in an atmosphere-only configuration, using sea surface temperatures, sea ice conditions, surface water dimethyl sulphide and chlorophyll concentrations, vegetation distribution, leaf area index, and canopy heights representative of a pre-industrial (PI; Year 1850) state. These climatologies, including a seasonal cycle, were calculated using 30 years output from the coupled (atmosphere-ocean) PI control experiment of UKESM1 (*piControl*), characterised in Sellar et al. (2019) and run as part of the 6th Coupled Model Intercomparison Project (CMIP6; Eyring et al., 2016).

The experiments conducted here consist of paired simulations: a PI (Year 1850) timeslice simulation and a parallel simulation, in which the global mean CH_4 concentration prescribed as a lower boundary condition in the model is changed from its Year-1850 value (808 ppb) to its present-day (PD; Year 2014) value (1831 ppb) based on CMIP6 recommendations from Meinhausen et al. (2017). CH_4 concentrations aloft are simulated interactively by the model. The initial pair follows the protocol from the Aerosol and Chemistry Model Intercomparison Project (AerChemMIP; Collins et al., 2017) and are called *piClim-control* and *piClim-CH4* , respectively. All other model settings in the experiments are representative of the PI period using CMIP6 recommendations. Briefly here, other GHG concentrations are prescribed according to Meinhausen et al. (2017). Gas-phase and aerosol-phase anthropogenic and biomass burning emissions for the PI period are taken from Hoesly et al. (2018) and van Marle et al. (2017), respectively. Natural volcanic and solar forcings were fixed in all simulations at Year-1850 levels (Arfeuille et al., 2014; Thomason et al., 2018; Matthes et al., 2017) using those specified for CMIP6 (Eyring et al., 2016). Further details are provided in O'Connor et al. (2021)

The apportionment of the total CH_4 ERF between direct and indirect ERFs is calculated in two ways. The first approach is called the "Elimination Method", whereby additional pairs of simulations incrementally disable an interaction or forcing agent from influencing the TOA radiative fluxes, until the last pair only allows CH_4 itself to affect the TOA, thereby giving the direct CH_4 ERF. The difference between successive pairs is then used to infer the proportion of the total CH_4 ERF to that particular indirect effect, forcing agent or interaction assuming linearity.

As mentioned, the final pair above gives the direct CH_4ERF . Similarly, other paired experiments are conducted, such that the ERF associated with a single composition change or interaction is calculated directly rather than inferring it from differencing two pairs. This methodology is referred to as the "Single Forcing Method" and gives rise to smaller errors than the "Elimination Method". All the experiment pairs carried out for this study using the two methods are listed in Table 1 and were run for 45 years, with the latter 30 years used for analysis.

The ERF itself is calculated from the difference in the TOA radiative fluxes between a perturbation experiment (e.g., piClim-CH4) and its control experiment (e.g., piClim-control) as follows:

 $ERF = \Delta F$, (1)

where F includes the IRF as well as other changes to the TOA radiative fluxes due to rapid adjustments. Although strictly by definition, the ERF should exclude land surface temperature adjustments, model experimental protocols and recommendations for quantifying ERFs to date (e.g., Forster et al., 2016; Pincus et al., 2016; Collins et al., 2017) fix sea surface and sea ice conditions only. Hence, the ERFs quantified here include a contribution from temperature adjustments over the land surface. However, this contribution was found to be small in the case of the CH₄ ERF – typically 0.02-0.03 W m⁻² (Thornhill et al., 2021b) but is much larger for CO₂ forcing (Andrews et al., 2021).

The ERF can be decomposed into the clear-sky component (ERFcs) and the change in the cloud radiative effect (ΔCRE) as follows:

$$ERF = \Delta Fcs + \Delta (F - Fcs) (2) = ERFcs + \Delta CRE, (3)$$

where Fcs is the clear-sky (CS) radiative flux. Due to the potential of the CH₄ perturbation to alter atmospheric oxidants and secondary aerosols in UKESM1 leading to "cloud masking" (e.g., Zelinka et al., 2014), Δ CRE is diagnosed from "clean" radiation calls that exclude aerosol-radiation interactions (ari), as recommended in Ghan (2013):

 $ERF = \Delta(F - Fclean) + \Delta Fcs, clean + \Delta(Fclean - Fcs, clean)(4)$ $ERF = Aerosol \ IRF + ERFcs, clean + \Delta CRE' \ (5)$ $ERF = ERFcs' + \Delta CRE'. \ (6)$

The ERF is, thus, separated into a component due to cloud property changes ($\Delta CRE'$) and the non-cloud forcing (ERFcs'). Here, ERFcs' is the sum of the aerosol IRF and any non-aerosol changes in CS fluxes (due to CH₄, O₃, etc.) and differs slightly from ERFcs in Eqn. (3), in that it can include the impact of aerosol scattering and absorption in the clear-air above or below clouds. This is the approach adopted by O'Connor et al. (2021) in quantifying a wide range of PD anthropogenic ERFs in UKESM1. However, it is worth noting that $\Delta^{c}PE'$, as defined here, differs from the cloud adjustment in Thornhill et al. (2021b). In that study, the cloud adjustment is estimated from $\Delta CRE'$ but corrects for cloud masking using kernel-derived non-cloud adjustments and the non-aerosol IRF.

For each pair in Table 1, the ERF is calculated as the time-mean global-mean difference in the TOA radiative fluxes, using the latter 30 years of the 45-year long simulations and decomposed into its components following Eqn. (6) and O'Connor et al. (2021). In addition to the "Elimination Method" and "Single Forcing Method"

simulation pairs (Table 1), the TOA IRF from the CH_4 -driven changes in aerosols was diagnosed through a double call to the radiation scheme (Ghan et al., 2012) in order to quantify the contribution of the aerosol IRF to *ERFcs*' in Eqn. (6). ERF estimates and their components from the different methods can be found in Tables 2 and 3 and will be discussed in Sect. 3.

The UKESM1 simulations conducted here (Table 1) were also complemented with offline calculations using the ESM's radiation scheme SOCRATES (Suite of Community Radiation Codes based on Edwards and Slingo, 1996). The offline SOCRATES experimental setup followed the PI aerosol- and cloud-free protocol from the Radiative Forcing Model Intercomparison Project (RFMIP; Pincus et al., 2016), designed to test the accuracy of clear-sky radiative transfer parameterizations on global scales. The setup consists of 100 profiles of PI atmospheric conditions including GHG concentrations (called PI here), that when weighted appropriately and averaged, approximate to global annual mean PI radiative fluxes. A parallel perturbation setup consists of an atmosphere, in which all conditions remain at PI levels except for a PI-to-PD perturbation in CH_4 concentration (called *PI-CH*₄). Together, *PI* and *PI-CH*₄ are representative of the UKESM1 simulations piClim-control and piClim-CH4, respectively, and the difference in radiative fluxes gives the direct CH₄ IRF. A second perturbation setup is representative of a PI atmosphere, but the only perturbation applied is the CH_4 -driven O_3 change diagnosed from UKESM1 (called PI-O3). Together, PI and PI-O3 mimic the Single Forcing Method #3 pair of UKESM1 simulations (Table 1) and the difference in radiative fluxes yields the indirect O_3 IRF. In a similar way, the indirect WV IRF can be diagnosed by quantifying the difference in radiative fluxes between PI and PI-WV, where PI-WV is representative of a PI atmosphere but with the UKESM1 CH₄-driven change in WV diagnosed applied.

3 Results

The total PD (Year 2014) CH₄ ERF relative to the PI (Year 1850) period is 0.97 ± 0.04 W m⁻² (O'Connor et al., 2021; Table 2), where the 0.04 W m⁻² is the standard error following Forster et al. (2016). Previous studies have found that CH₄ forcing is almost double that of the direct CH₄ forcing (Shindell et al., 2005; Myhre et al., 2013). This is also evident here, with the direct CH₄ERF estimated to be half (0.54 +- 0.04 W m⁻²; Table 2) that of the total CH₄ ERF due to indirect effects. These indirect effects result from changes in O₃, stratospheric WV, and potentially aerosols. Tables 2 and 3 provide the indirect ERFs from O₃ and WV; estimates from the two methods agree to within their error bars: 0.13 +- 0.05 W m⁻² from the Elimination Method and 0.20 +- 0.04 W m⁻² from the Single-Forcing Method for O₃ and 0.07 +- 0.05 W m⁻²/0.02 +- 0.04 W m⁻² for WV.

The ERF estimates also suggest that the total CH_4 ERF from UKESM1 includes a significant indirect contribution from aerosols, particularly aerosol-cloud interactions (aci). As was the case for O₃ and WV, the indirect ERFs from the two methods agree to within their error bars for both aci (0.28 +- 0.06 W m⁻² from the Elimination Method and 0.30 +- 0.04 W m⁻² from the Single Forcing Method; Tables 2 and 3) and aerosol-radiation interactions (ari) (-0.05 +- 0.06 W m⁻²/0.00 +- 0.04 W m⁻²). The results also indicate that the direct and indirect ERFs are additive and that they add up linearly. For example, the total CH_4 ERF (0.97 +- 0.04 W m⁻²; Table 2) closely matches the sum of the individual direct and indirect ERFs (1.06 +- 0.09 W m⁻²; Table 3).

Apportionment of the forcing using the Elimination and Single-Forcing pairs in this way may help to explain some of the spread in PD CH₄ ERF estimates from the AerChemMIP multi-model ensemble (Thornhill et al., 2021b) and provide a process-based understanding of the positive cloud adjustment in UKESM1. The direct CH₄ ERF and the indirect ERFs from O_3 , WV, and aerosols in UKESM1 and the relevant changes in composition are discussed further in the following sections.

3.1 Composition Changes

Figure 1 shows multi-annual mean pre-industrial (*piClim-control*) distributions of O_3 , WV, Aitken and accumulation mode aerosol number concentrations, and aerosol optical depth (AOD), as well as changes due to the PI-to-PD increase in CH₄concentration (*piClim-CH*4 minus *piClim-control*). It shows that in the PI atmosphere, O_3 concentrations show a maximum in the tropical stratosphere of greater than 10 ppmv,

with minimum concentrations aloft and in the troposphere (Figure 1a). As a tropospheric O_3 precursor, the CH_4 increase gives rise to an increase in tropospheric O₃ concentrations of 10-20 % on a zonal annual mean basis (Figure 1b). Reductions of 0-10 % in stratospheric O₃ concentrations also occur, reflecting the complex interactions between CH_4 and stratospheric O_3 due to both the direct impact of CH_4 on the odd hydrogen (HOx) loss cycle (Pawson et al., 2014) and the indirect impact of CH₄-induced increases in stratospheric WV (e.g., Stenke and Grewe, 2005). This reduction is lower than the 15 % reduction in O₃ following a 2-fold increase from PD CH_4 concentrations in Winterstein et al. (2019) although their simulations had PD chlorine loading. They also showed increases in WV of up to 50 % in the middle and higher stratosphere. Here, the CH₄ perturbation represents more than a doubling of the global mean PI concentration and we find maximum increases in WV of over 30 % (Figure 1d). The CH₄ perturbation also gives rise to changes in other oxidants (e.g., OH), causing the total CH_4 lifetime to increase from 8.1 years in *piClim-control* to 9.8 years in *piClim-CH*4 (O'Connor et al., 2021). In turn, this change in oxidants leads to a change in the global distribution of AOD. In particular, the low background aerosol loading in the PI atmosphere, which has implications for PD anthropogenic aerosol forcing (Carslaw et al., 2013), sees some regional increases and decreases of over 5 % in magnitude (Figure 1j). Indeed, Shindell et al. (2009) found an aerosol forcing attributable to a PI-to-PD change in CH_4 although in that study, a change in sulfate burden on a global scale was more evident (-11 %). Here, the global mean AOD changes by less than 2 %; the regional changes are limited in spatial extent and statistical significance, and have opposing signs.

However, statistically significant differences are more evident in the aerosol size distribution. For example, PI Aitken mode number concentrations peak at more than 1000 cm⁻³ in the tropical mid-troposphere (Figure 1e). The PI-to-PD CH₄ concentration perturbation leads to reductions in Aitken mode number concentrations throughout the troposphere, with a maximum reduction of up to 50 cm⁻³ (Figure 1f). Likewise, accumulation mode number concentrations peak near the surface in the tropics and the northern hemisphere mid-latitudes in the PI period (Figure 1g), with values of over 100 cm⁻³ and reductions of up to 10 cm⁻³ resulting from the CH₄perturbation (Figure 1h). Given the weak and limited spatial extent of the changes in AOD, these reductions in Aitken and accumulation mode number concentrations are commensurate with increases in coarse mode number concentration (not shown). These results support the findings that the indirect contribution to the total PD CH₄ ERF from aerosol-radiation interactions (ari) in UKESM1 is small (Tables 2 and 3) and that the CH₄-driven change in the aerosol size distribution has the potential to contribute significantly to the CH₄ ERF through aerosol-cloud interactions (aci; Tables 2 and 3). This is explored further in Sect. 3.4.

3.2 Direct Methane Effective Radiative Forcing (ERF)

The direct CH_4 ERF at the PD relative to the PI period is 0.54 +- 0.04 W m⁻² (Tables 2, 3), consistent with the traditional stratospherically-adjusted radiative forcing (SARF) estimate from the updated expression from Etminan et al. (2016) i.e., 0.56 W m⁻². As was the case for the total CH_4 ERF (Table 2), the majority of this forcing is in the clear sky (CS) longwave (LW) component (0.60 +- 0.02 W m⁻²), with the CS shortwave (SW) contribution to the ERF $(0.07 + 0.02 \text{ W m}^{-2})$ being more than offset by the cloud radiative effect (CRE) (-0.14 +- 0.04 W m⁻²). The negative CRE in the direct CH₄ ERF from UKESM1 is consistent with Smith et al. (2018). In that study, only those models that included SW absorption by CH_4 had a negative cloud adjustment; the SW absorption causes tropospheric heating and reductions in upper tropospheric cloud amounts. However, in comparing with the direct CH_4 ERF from the HadGEM2 model (Collins et al., 2011) from Andrews (2014) in Table 4, there is good quantitative agreement between the net $CS (0.68 + -0.03 \text{ cf. } 0.61 \text{ W m}^{-2})$ and the net CRE (-0.14 + -0.04 cf. -0.11 W m⁻²) components. However, there is poor agreement with the individual CS SW (0.07 +- 0.02 cf. -0.13 W m⁻²) and LW (0.60 +- 0.02 cf. 0.74 W m^{-2}) components, which cannot be reconciled by the different years representing the PI and PD in the two studies. Indeed, UKESM1 shows a positive CS forcing in the SW consistent with Etminan et al. (2016) whereas HadGEM2 has a non-zero CS forcing despite no treatment of solar absorption by CH_4 . HadGEM2 also shows a larger CS LW forcing than UKESM1, which could be related to the lack of treatment of CH_4 in the SW (Collins et al., 2006; Li et al., 2010; Etminan et al., 2016). However, the anomalous negative CS SW component in the HadGEM2 simulations offsets its stronger positive CS LW component, resulting in the two models having comparable net CS components for the direct CH_4 ERF.

To investigate the differences between HadGEM2 and UKESM1 further, we make use of the study by Smith et al. (2018) which found that the direct CH_4 ERF is approximately equal to its instantaneous radiative forcing (IRF), due to the rapid adjustments included in the ERF either being small or summing to zero. As a result, the idealised stand-alone PI test case from the RFMIP protocol (Pincus et al., 2016) can be used here to investigate the differences in the direct CH_4 ERF CS components between HadGEM2 and UKESM1.

As outlined in Sec. 2, the main test case used from RFMIP is that of a cloud-free aerosol-free PI atmosphere - referred to here as PI. A parallel perturbation test case ($PI-CH_4$) with the PI-to-PD perturbation applied was set up, with both test cases run using the corresponding spectral data files from HadGEM2 and UKESM1. Figure 2 shows profiles of the differences in the SW, LW and net outgoing radiative fluxes between the two test cases ($PI-CH_4$ minusPI). It shows that with the HadGEM2 spectral data, the SW IRF at TOA under aerosol-free cloud-free conditions is expected to be zero. It also shows that the small positive CS SW ERF from the UKESM1 simulation is consistent with the SW IRF at TOA calculated offline. Looking at the LW fluxes, the difference in the CS LW ERF between HadGEM2 and UKESM1 is mostly explained by the updated spectroscopic data used in UKESM1 relative to HadGEM2 (Walters et al., 2019), although some discrepancy (~0.06 W m⁻²) still remains. A sensitivity test with offline SOCRATES using 3D CH₄fields from UKESM1 rather than constant CH₄concentrations throughout the depth of the atmosphere, at most, accounts for only 0.01 W m⁻².

Although the stand-alone tests support the findings from UKESM1 in both the CS SW and LW components of the direct CH₄ ERF, they do not explain the non-zero (or negative) CS SW forcing in HadGEM2. Further investigations into the HadGEM2 simulations show that the negative CS SW ERF was due to changes in dust outflow from North Africa; the 3 CH₄ perturbation experiments showed significant variability in the CS SW ERF i.e., -0.04 to -0.28 W m⁻², with the -0.13 W m⁻²reported in Andrews (2014) being the average of the 3 ensemble members. It is still unclear what mechanism is driving the dust response in HadGEM2 but dust production in that model was found to be highly sensitive to various atmospheric and surface variables (Collins et al., 2011). Nevertheless, the results indicate that the direct CH₄ ERF is better represented in UKESM1 than in HadGEM2 and is more consistent with the Etminan et al. (2016) expression based on line-by-line radiative transfer calculations. UKESM1 is also more consistent with the multi-model mean of the IRF due to a PD-to-PI CH₄ perturbation from present day in Pincus et al. (2020). This improvement in UKESM1 is three-fold: (i) the inclusion of SW absorption by CH₄, (ii) the update to the LW spectral data for CH₄, and (iii) the absence of an anomalous dust response in the UKESM1 CH₄ perturbation experiments.

3.3 Methane-Driven Ozone and Water Vapor ERFs

As seen from Figure 1, the PI-to-PD perturbation increases tropospheric O_3 and decreases stratospheric O_3 , changes which together contribute an indirect O_3 ERF to the total CH₄ ERF. Using the "Elimination Method" and "Single Forcing Method", we calculate an indirect O_3 ERF attributable to the PI-to-PD change in CH₄concentration of 0.13 +- 0.05 and 0.20 +- 0.04 W m⁻², respectively, showing good consistency between the two methods. This positive forcing is predominantly in the CS (0.18 +- 0.04/0.24 +- 0.03 W m⁻²; Tables 2, 3) and in the LW (0.19 +- 0.02/0.17 +- 0.02 W m⁻²; Tables 2, 3), reflecting the sensitivity of forcing per unit mass to the vertical distribution of O_3 changes (Lacis et al., 1990) and the dominance of the tropospheric O_3 change to the ERF (Skeie et al., 2020). There is a very weak CRE (-0.07 +- 0.05/-0.04 +- 0.04 W m⁻²; Tables 2, 3) but given the standard errors, its contribution to the indirect O_3 ERF and the total CH₄ ERF can be considered negligible. This is consistent with Skeie et al. (2020), who found that the cloud adjustment associated with O_3 forcing is small (~0.02 W m⁻²), albeit opposite in sign to that found here.

It is also worth noting that water vapor (WV) production from CH_4 oxidation was switched on when isolating the indirect O_3 ERF using the "Elimination Method" (Table 1). This has the potential for the indirect O_3 ERF to include the radiative effect of O_3 changes resulting from CH_4 -driven increases in stratospheric WV (e.g., Stenke and Grewe, 2005) in addition to the radiative effect of more direct CH_4 -driven changes in tropospheric and stratospheric O_3 . On the other hand, for the "Single Forcing Method", the O_3 ERF was quantified with WV production from CH_4 switched off. Hence, the smaller magnitude of the inferred O_3 ERF compared with that from the Single Forcing method could be due to a difference in O_3 in the model simulations from WV. However, the magnitude of the difference in the O_3 change was less than 2 %, with regional differences of opposing sign; the resulting impact on the indirect O_3 ERF can be considered negligible given the magnitude of the errors.

The study by O'Connor et al. (2021) found that the stratospherically-adjusted radiative forcing (SARF) from changes in tropospheric O_3 due to the PI-to-PD change in CH₄ concentration is 0.14 W m⁻². Taking a whole-atmosphere perspective, we estimate a whole-atmosphere O_3 SARF attributable to the PI-to-PD change in CH₄ concentration of 0.15 W m⁻² by combining the O_3 IRF calculated offline using SOCRATES (0.11 W m⁻²) with the stratospheric temperature adjustment (0.04 W m⁻²) calculated using a temperature radiative kernel (Smith et al., 2018). This suggests that the contribution from the stratospheric O_3 SARF is at most 0.01 W m⁻². It confirms that although the O_3 reductions in the upper stratosphere are substantial (0-20 %), the global mean stratospheric changes contribute little to the indirect whole-atmosphere O_3 SARF. This is as a result of O_3 forcing being dominated by changes in the upper troposphere and lower stratosphere (UTLS) (Lacis et al., 1990; Skeie et al., 2020) and the lack of atmospheric O_3 forcing in the future as concentrations of ozone-depleting substances decrease (e.g., Iglesias-Suarez et al., 2018). In particular, including troposphere-stratosphere chemistry schemes into ESMs (e.g., Morgenstern et al., 2017) provides additional insight into climate change drivers and has greater relevance for policy makers (Shindell et al., 2013).

In addition to O_3 , water vapor (WV) is also an effective GHG close to the tropopause (Lacis et al., 1990; Forster and Shine, 2002) and thus WV production from CH_4 oxidation has the potential to exert an indirect forcing. However, previous studies (e.g., Hansen et al., 2005; Myhre et al., 2007) have found the indirect stratospheric WV SARF to be small; AR5 concluded that it is in the range of 0.02 to 0.12 W m⁻² with a central estimate of 0.07 W m^{-2} (Myhre et al., 2013). This is due to the change in WV close to the troppause being small (Hansen et al., 2005). In this study, the change in the UTLS region is estimated to be less than 10 %. Larger changes in WV occur in the upper stratosphere but being optically thin and convectively stable, the changes there are less effective at influencing the radiative balance (Hansen et al., 2005). For comparison purposes, we quantify the WV SARF in two ways. Firstly, scaling the direct CH_4 SARF of 0.54 W m⁻² from Etminan et al. (2016) by 15 %, as done in the Intergovernmental Panel on Climate Change (IPCC) 4th assessment report (Forster et al., 2007), yields 0.08 W m⁻². Secondly, using the model-diagnosed changes in WV and temperature yield a TOA IRF of 0.05 W m⁻² and a stratospheric temperature adjustment of 0.04 W m⁻² from offline SOCRATES and a radiative kernel (Smith et al., 2018), respectively, we estimate a UKESM1-derived SARF of 0.09 W m⁻². Both estimates are consistent with the range from previous studies (Hansen et al., 2005; Myhre et al., 2007; Myhre et al., 2013). The indirect TOA ERFs quantified here by the "Elimination" and "Single Forcing" methods $(0.07 + 0.05/0.02 + 0.04 \text{ W m}^{-2}; \text{ Tables 2, 3})$ are consistent with each other but in the case of the Single Forcing method, the estimate appears to be marginally weaker than the SARF estimates. This indicates that there may be rapid adjustments other than the stratospheric temperature adjustment and that forcing estimates may be sensitive to the choice of metric (e.g., Smith et al., 2018). Nevertheless, the stratospheric WV forcing here is weakly positive and the choice of forcing metric does not have a major impact on the understanding of the role of CH_4 -driven changes in WV in the PD forcing of climate.

3.4 Methane-Driven Aerosol ERF and Cloud Radiative Effect

A significant finding of this study is that increases in CH₄ concentration lead to changes in aerosol properties resulting in a positive contribution to the total CH₄ERF. This aerosol-mediated term is estimated to be 0.23 + 0.06 or 0.30 + 0.06 W m⁻², depending on whether the "Elimination Method" or "Single Forcing Method" is used (Tables 2 and 3). This forcing is almost entirely from aerosol-cloud interactions (aci) and their influence on the SW radiative effects of clouds. The aci component is estimated to be 0.28 + 0.06/0.30 + 0.04 W m⁻² (Table 2, 3) and the aerosol-radiation interactions (ari) component is either weakly negative or neutral at -0.05 +- 0.06/0.00 +- 0.04 W m⁻² (Table 2, 3). A double call to the radiation scheme following Ghan et al. (2012) confirms that the magnitude of the CH₄-driven aerosol IRF is less than 0.01 W m⁻², consistent with the near-zero ari term derived from the Elimination and Single-Forcing methods. This is also consistent with the global mean AOD change only being of the order of 2 % (Figure 1). The explanation for the relatively substantial aci component lies in more subtle changes to aerosol size distributions and number concentrations. These appear to have been triggered by changes in oxidation rates affecting secondary aerosol formation and the nucleation of new particles. These following sub-sections explore these processes in further detail.

3.4.1 Aerosol-cloud microphysical changes

As shown in Figure 1, the PI-to-PD increase in CH_4 leads to statistically significant reductions in aerosol number concentrations, particularly across the Aitken mode, but also in the accumulation mode. This is also clear from examining the aerosol size distribution (Figure 3), where particle concentrations reduce most in relative terms across the size range from 20 - 200 nm in diameter (10 - 100 nm radius), encompassing the Aitken mode and much of the accumulation-mode peak. Crucially, the number of particles greater than 50 nm in diameter (N50) has reduced and this is likely to affect the availability of cloud condensation nuclei (CCN). The reduction of particle number concentrations appears to be driven by a reduction in the nucleation of new particles in the upper troposphere (Figure 4a). This is a region of the atmosphere where nucleation is typically most intense in the model so the reduction affects aerosol numbers globally. Indeed, there is a drop in zonal mean N50 across all latitudes and through the depth of the troposphere (Figure 4b). This follows through to a reduction in cloud droplet number concentration (CDNC) across all latitudes and heights in the multi-annual zonal means (Figure 4c) where liquid clouds are present in the model. The changes in N50 vary regionally as do the impacts on CDNC (Figure 5a, b). The strongest reductions in CDNC at 1 km occur over the oceans, especially in tropical and sub-tropical latitude zones where stratocumulus typically reside. These are statistically significant across most ocean regions and, as expected, lead to significant increases in cloud droplet effective radius (Reff) at 1 km, averaging around 0.1 - 0.2 µm over much of the oceans (Fig. 5c). The results strongly indicate that the so-called Twomey effect (Twomey, 1977) is weakened in the *piClim-CH4* simulation relative to *piClim-control*, resulting in less reflective clouds and the positive indirect ERF from aci of $0.28 \pm 0.06/0.30 \pm 0.04$ W m⁻² (Tables 2, 3). Although defined differently, the estimated aci response here is consistent with the UKESM1 cloud adjustment of $0.24 \text{ W} \text{ m}^{-2}$ from the radiative kernel difference method used in Thornhill et al. (2021b) - this is due to the corrections for cloud masking in Thornhill et al. (2021b) cancelling out or being equal to zero in the approaches (Elimination Method or Single Forcing Method) used here.

3.4.2 Aerosol-chemical feedback mechanisms

To understand why such changes in aerosol microphysics have occurred requires a more detailed investigation of changes in oxidation rates and the life cycle of aerosol-chemical processes. Table 5 shows a full gas-phase and aerosol budget for sulfur species and organic matter (OM) from the piClim-control and piClim-CH4 simulations and Figure 6 shows a schematic of the main processes involved in the secondary formation of sulfate (SO₄) aerosol in UKESM1 (Sellar et al., 2019). Dimethyl sulphide (DMS) is oxidised in the gas phase to form sulfur dioxide (SO_2) . In the PI atmosphere, DMS is oxidised by the hydroxyl (OH) radical $(14.38 + 0.09 \text{ Tg} (S) \text{ yr}^{-1})$, nitrate $(2.03 + 0.03 \text{ Tg} (S) \text{ yr}^{-1})$ and oxygen atoms $(0.18 + 0.01 \text{ Tg} (S) \text{ yr}^{-1})$. Together with carbonyl sulphide (COS) photolysis and oxidation, they account for 16.72 + 0.10 Tg (S) yr⁻¹ of the PI global SO₂ source. The remaining SO₂ source is primary, amounting to 14.82 Tg (S) yr⁻¹. SO₂ is then oxidised by OH and O_3 in the gas phase and by hydrogen peroxide (H_2O_2) and O_3 in the aqueous phase (Table 5), with the 3 principal pathways shown in Figure 7. Oxidation by OH accounts for 40.7 % of PI SO_2 oxidation to produce sulfuric acid (H_2SO_4). New particle formation arises from the binary homogeneous nucleation of H_2SO_4 and water in the free troposphere (Vehkamaki et al., 2002), leading to an increase in nucleation mode number concentration and SO_4 aerosol mass (Figure 6) and accounting for 0.8 % of PI secondary SO₄ aerosol production. Gas-phase H₂SO₄ also condenses onto pre-existing aerosol, increasing SO_4 mass without changing aerosol number concentration and contributes 46.7 % to the secondary SO_4

aerosol production. SO₂ is also oxidised via dissolution into cloud droplets followed by reaction with H_2O_2 or O_3 . Fluxes from these aqueous-phase reactions update the SO₄ mass in both the accumulation and coarse mode aerosol with no change in aerosol number concentration, and account for 43.3 and 9.1 % of secondary SO₄ production, respectively. The resulting PI SO₄ burden is 0.456 +- 0.005 Tg (S). Wet scavenging accounts for up to 85 % of SO₄ aerosol removal, leading to a lifetime of 9.17 +- 0.12 days.

Table 5 indicates that in the PI atmosphere, primary emissions of OM from land and marine sources contribute 49.25 +- 0.01 Tg (OM) yr⁻¹, with the latter coupled to the ocean biogeochemistry scheme (Sellar et al., 2019; Mulcahy et al., 2020). Secondary formation of OM is via oxidation of monoterpenes and the gasphase product condenses onto pre-existing aerosol (Kelly et al., 2018; Mulcahy et al., 2020) i.e., increasing OM aerosol mass but with no change in aerosol number concentration. In the PI atmosphere, secondary formation of OM aerosol accounts for 43.7 % of the global OM source. Close to 80 % of OM is removed by wet scavenging, with the remainder by dry deposition, leading to a PI aerosol burden of 1.28 +- 0.02 Tg (OM) and a lifetime of 5.29 +- 0.05 days. A full description of the GLOMAP-mode aerosol scheme and its performance in UKESM1 for the recent past can be found in Mulcahy et al. (2020).

In *piClim-CH*⁴, the PI-to-PD increase in CH₄ concentration does not change the total DMS source or DMS oxidation flux relative to the PI atmosphere (Table 5). However, CH₄-driven changes in oxidants change the relative contributions of the different DMS oxidation pathways. For example, oxidation by OH reduces by 4% while oxidation by NO₃ increases by 22 %. These changes are most evident in the DMS burden over the Southern Ocean, where reductions in oxidation by OH change the regional distribution of secondary sources of SO₂ (not shown). On a global annual mean basis, the DMS burden and lifetime both increase (Table 5).

The PI-to-PD increase in CH₄ also alters the relative contribution of the different SO₂ oxidation pathways (Figure 7). Oxidation of SO₂ by OH reduces from 8.01 +- 0.07 Tg (S) yr⁻¹ to 6.83 +- 0.06 Tg (S) yr⁻¹ - a decrease of 14.7 %. Oxidation by H₂O₂ increases by 12.4 % and accounts for over 50 % of SO₂ oxidation. There is little change in the aqueous-phase oxidation by O₃(+0.2 %) or in the total amount of SO₂ being oxidised, as was the case for DMS. The change in oxidation by OH is consistent with the CH₄ lifetime increasing by 21 % in *piClim-CH*₄ relative to *piClim-control* (O'Connor et al., 2021). Given that the gas-phase oxidation of SO₂ by OH is the only pathway that gives rise to new particle formation in UKESM1, a change in the relative contributions of the different SO₂ oxidation pathways *alone* may lead to a change in aerosol size distribution and hence, cloud activation (Abdul-Razzak and Ghan, 2000). A similar mechanism, albeit due to sensitivity of the aqueous-phase oxidation of SO₂ by O₃ to changes in cloud water pH, was found to affect aerosol formation rates, cloud activation, and aerosol forcing by Turnock et al. (2019) although the pH is fixed in the configuration used here (Mulcahy et al., 2020).

Due to oxidant changes, the CH₄ increase in *piClim-CH*₄ leads to less new particle formation; nucleation rates of H₂SO₄ decrease from 0.137 +- 0.003 to 0.126 +- 0.003 Tg (S) yr⁻¹, amounting to a decrease of 8.0 %. This helps to explain why the concentration of nucleation-mode particles has reduced (Figure 4a). Condensation of gas-phase H₂SO₄ also decreases, with the smallest and largest reductions evident in condensation rates onto the nucleation and coarse modes of 8.3 and 21.1 %, respectively. On the other hand, condensation rates onto accumulation and coarse mode aerosol following aqueous-phase oxidation of SO₂ via H₂O₂ increase from 7.20 +- 0.04 to 8.08 +- 0.06 Tg (S) yr⁻¹. The net effect of these changes is that there is less SO₄ mass in the nucleation (-1.8 %) and accumulation (-3.8 %) modes, with a very marginal increase in the Aitken mode (less than 1 %) and a near-zero change in the coarse mode. Together, these combine to give a SO₄ burden in *piClim-CH*₄ of 0.446 +- 0.005 Tg (S), which is only 2 % lower than in the PI atmosphere.

In the case of OM, CH₄ changes the relative contributions of the different monoterpene oxidation pathways although the total secondary production of OM is unchanged. Oxidation by OH decreases by 4.8 %, while oxidation by NO₃ and O₃ increase by 2.1 and 2.4 %, respectively. As a result, the monoterpene burden reduces by 6 % in the global annual mean. Secondary OM production, via condensation onto pre-existing aerosol of the condensable vapour product from monoterpene oxidation, remains unchanged (Table 5). However, condensation onto the nucleation and Aitken soluble modes decreases by 4.6 and 1.5 %, respectively, while that onto the Aitken insoluble, accumulation and coarse modes increases marginally. This is suggestive that changes in gas-to-particle partitioning of OM onto pre-existing aerosol also have the potential to modulate the aerosol size distribution further. Although the total OM burden is unchanged, there is less OM mass in all modes, except for the Aitken insoluble mode. Less mass in the smaller modes also reduces the condensational growth of particles to sizes that can contribute to CCN, thereby directly leading to a shift in the aerosol size distribution (Figure 3) towards one with fewer particles large enough to act as CCN (Figure 4) and a weakening of the Twomey effect (Section 3.4.1).

3.5 Thermodynamic feedbacks on cloud

The analyses presented in Table 2 and 3 show that the cloud radiative effect (CRE) played a significant role in the CH₄ ERF. In total, the CRE accounts for 0.12 W m⁻² of the total CH₄ ERF (with all interactions included) but the individual SW and LW components are much larger (0.50 W m⁻² for SW and -0.38 W m⁻² for LW). Whilst the aci were a strong contributor to the SW CRE (amounting to 0.28 – 0.30 W m⁻²) and wholly responsible for the cloud adjustment as defined in Thornhill et al. (2021b), some 0.23 W m⁻² of the SW CRE occurs with aci disabled. The negative LW CRE component is driven almost exclusively by the nonaerosol interactions; the perturbations in CH₄, WV and O₃ together build towards the negative LW CRE of -0.35 W m⁻² in the absence of the aci. It is therefore clear that much of the change in the CRE are related to thermodynamic feedbacks, such as changes in temperature and atmospheric circulation, rather than microphysical interactions.

To investigate such thermodynamic feedbacks, we analyse the pair of simulations with PI or PD CH₄ where interactive aci were eliminated (as listed in the second row of Table 2). There are increases in temperature in the troposphere (Figure 8a), especially in the upper troposphere and the warming peaks at around 0.5 K across the tropical tropopause. Some cooling occurs at higher levels in the stratosphere. Along with the warming patterns are statistically significant reductions in cloud fractions (Figure 8b). For instance, in the deep tropics, cloud cover has reduced at mid and upper levels of the troposphere, which is indicative of suppressed convection associated with the warming and stabilization of the troposphere. There are also statistically significant reductions in cloud cover in the mid-latitudes around 45 oS and 40 oN that extend through the range of the troposphere. At high latitudes, there appears to be strong changes in cloud of both positive and negative sign, but these are not statistically significant. Overall, the global-mean cloud fraction reduces by 0.25 % and there were decreases of 1.0 and 0.9 % in global-mean liquid water path and ice water path, respectively. The decreased cloud explains the negative LW CRE (increased outgoing LW), and positive SW CRE (less reflection). In addition, global-mean precipitation decreases by 0.013 mm/day (0.4%), indicating that there was a slight slowing down of the hydrological cycle. This is consistent with the suppression of convection, which is expected for forcing agents that increase absorption of radiation in the troposphere. The CH_4 contributes SW and LW absorption (Figure 2) and increased tropospheric O_3 contributes to the absorption of SW in the troposphere. These decreases in precipitation, cloud and CRE can be regarded as so-called "rapid responses" (e.g. Smith et al., 2018), since the sea surface temperatures in these simulations were fixed. Slow feedbacks from longer-term climate warming could be different or even have the opposite tendency to the fast feedbacks.

3.6 Emission-Based Estimates of Forcing

The direct and indirect CH_4 ERFs quantified here are based on the observed change in global mean concentration between 1850 and 2014 (Meinhausen et al., 2017) and are referred to as concentration-based or abundance-based ERFs. The abundance-based approach used here is similar to that taken for previous estimates of the direct and total CH_4 forcing (Andrews, 2014; Etminan et al., 2016; Smith et al., 2018; O'Connor et al., 2021; Thornhill et al., 2021b). However, the chemical coupling between CH_4 and its own sink, via OH, means that an increase in CH_4 emissions decreases OH, increases the CH_4 lifetime, and increases the resulting atmospheric concentration (Prather et al., 2001). The CH_4 lifetime and atmospheric abundance also depend on emissions of other tropospheric O_3 precursors, with the PI-to-PD increase in volatile organic compound (VOC) and carbon monoxide (CO) emissions contributing to an increase in CH_4 lifetime whereas the increase in nitrogen oxides (NOx) emissions causes a decrease (Stevenson et al., 2020). Together, it means that the observed CH_4 concentration change is lower than would arise from the PI-to-PD change in CH_4 emissions *alone*. As a result, an emissions-based forcing estimate, based solely on the PI-to-PD increase in CH_4 emissions, could be larger than an abundance-based estimate by as much as 25 % (Shindell et al., 2005).

Outside of CMIP6, ESMs including UKESM1 are starting to include more interactive CH_4 cycles, with CH_4 emissions-driven rather than concentration-driven (Ocko et al., 2018; Kleinen et al., 2020; Folberth et al., 2021). Forcing estimates from an emissions-based perspective, in the case of CH_4 , provide a more direct attribution of the forcing to changing emissions and have greater relevance for policy makers (Shindell et al., 2013). Therefore, understanding and quantifying the potential differences in forcing between the current generation of CMIP6 models with CH_4 concentration-driven and those models driven by CH_4 emissions is important. Here, we attempt to convert the UKESM1 direct and indirect abundance-based CH_4 ERFs to emissions-based estimates.

To do this for the direct CH₄ radiative forcing and ERF, we make use of additional experiments from the AerChemMIP protocol (Collins et al., 2017): *piClim-NOx* and *piClim-VOC*, in which PI-to-PD perturbations to the anthropogenic emissions of (i) NOx and (ii) VOCs and CO were applied, respectively. The model-diagnosed change in total CH₄ lifetime in relation to*piClim-control* is used to calculate the equilibrium CH₄ concentrations from the *piClim-CH4*, *piClim-NOx* and *piClim-VOC* experiments following O'Connor et al. (2021). From the difference between the prescribed and equilibrium CH₄ concentrations and the UKESM1 direct CH₄ ERF, a PD emissions-based direct radiative forcing by CH₄ is estimated to be 0.67 W m⁻². This comprises the direct CH₄ concentration-based radiative forcing of 0.56 W m⁻² and additional individual contributions from CH₄, NOx, and VOCs/CO (via their influence on CH₄ lifetime) of 0.22, -0.19, and 0.08 W m⁻², respectively (Table 6). The estimate of 0.67 W m⁻² is almost 20 % larger than the concentration-based estimate of 0.56 W m⁻² from Etminan et al. (2016), and is consistent with the findings of Shindell et al. (2005). Using the direct CH₄ ERF from UKESM1 is 0.65 +- 0.05 W m⁻².

In relation to the indirect O_3 forcing from CH₄, the study by O'Connor et al. (2021) found that the tropospheric O_3 stratospherically-adjusted radiative forcing (SARF) for the year 2014 due to changes in CH₄since the PI period from concentration-based and emissions-based perspectives is 0.14 and 0.21 W m⁻², respectively. The emissions-based estimate is comparable to that from Shindell et al. (2005) for the year 1998 (0.20 W m⁻²) relative to 1750 despite the CH₄ concentration change in that study being larger than that applied here (1209 cf. 1023 ppb). However, they noted from their simulations that the O₃ response to a positive CH₄ perturbation at the PI is larger than a negative perturbation applied at the PD by 20 %. Therefore, scaling our emissions-based estimate by the ratio of the concentration changes between the two studies gives a revised UKESM1 estimate of 0.25 W m⁻² for the 1750-1998 period, which is indeed approximately 20 % larger than the estimate from their PD simulations. Taking the UKESM1 indirect abundance-based ERFs from O₃ of 0.13 +- 0.05 and 0.20 +- 0.04 W m⁻² from the Elimination (Table 2) and Single-Forcing (Table 3) methods, respectively, emission-based ERFs are likely to be 0.19 +- 0.07 and 0.30 +- 0.06 W m⁻², respectively. These ERF values are reasonably consistent with the SARF of 0.21 W m⁻² from O'Connor et al. (2021) and reflect that rapid adjustments in the O₃ ERF are small in magnitude and nearly sum to zero (Skeie et al., 2020).

In the case of stratospheric WV, adopting the approach of scaling the direct emissions-based CH₄ ERF of 0.65 W m⁻² by 15 % yields an indirect emissions-based ERF from WV of 0.10 +- 0.01 W m⁻². However, this seems rather high relative to the abundance-based ERF from the Single-Forcing Method of 0.02 +- 0.04 W m⁻² (Section 3.3). Therefore, as an alternative, we apply the ratio of the direct emissions-based to the abundance-based CH₄ ERFs to the indirect abundance-based WV ERF, leading to an estimate of 0.02 +- 0.05 W m⁻². Finally, although aci are non-linear, a similar approach leads to a potential emissions-based indirect ERF from aci of 0.35 +- 0.07 and 0.36 +- 0.05 W m⁻² from the Elimination and the Single-Forcing methods, respectively. Taking the emission-based ERFs from the Single-Forcing method alone, we calculate a total PD (Year 2014) emissions-based CH₄ ERF of 1.33 +- 0.11 W m⁻² relative to the PI (Year 1850) period. This is higher than the total abundance-based ERF by 37 % and highlights the importance of

historical changes in CH_4 emissions in the PD forcing of climate. It also emphasises the potential role of CH_4 in mitigating the near-term rate of climate change (Allen et al., 2018; Abernethy et al., 2021).

4 Conclusions

The PI-to-PD change in methane (CH₄) concentration from 808 to 1831 ppb leads to a global mean ERF of 0.97 +- 0.04 W m⁻² (O'Connor et al., 2021), with the majority of the forcing in the clear-sky (CS) longwave (LW) component. Of this forcing, the direct concentration-based CH₄ contribution is 0.54 +- 0.04 W m⁻² and is consistent with line by line radiative transfer calculations (Etiminan et al., 2016) and is better represented in UKESM1 than in its predecessor model, HadGEM2. An indirect O₃ ERF of 0.13 +- 0.05 W m⁻² from the Elimination Method and 0.20 +- 0.04 W m⁻² from the Single-Forcing Method is attributable to the CH₄ concentration increase, which is largely due to the tropospheric O₃ increase despite significant O₃ decreases in the stratosphere. The production of water vapor due to changes in CH₄ leads to a weakly positive ERF of 0.07 +- 0.05/0.02 +- 0.04 W m⁻² – these values are consistent with previous estimates based on the stratospherically-adjusted radiative forcing metric (Hansen et al., 2005; Myhre et al., 2013), suggesting that the choice of forcing metric does not have a major impact on our understanding of the role of CH₄-driven changes in WV in climate forcing.

The PI-to-PD CH₄ increase in concentration also gives rise to a positive aerosol ERF of 0.28-0.30 W m⁻²through aerosol-cloud interactions. CH₄-driven changes in oxidants, particularly OH, alter the relative contributions of the different sulfur dioxide (SO₂) oxidation pathways, leading to a reduction in new particle formation, a decrease in the number concentration of cloud condensation nuclei and cloud droplets, with a corresponding increase in cloud droplet effective radius. However, the forcing from aerosol-radiation interactions is negligible, consistent with the global mean aerosol optical depth changing by less than 2 %. This study also confirms that the strong positive cloud adjustment in UKESM1, as defined and quantified in Thornhill et al. (2021b), is aerosol-mediated.

Previous studies have found an aerosol forcing attributable to CH_4 and/or oxidant changes. Shindell et al. (2009), for example, found a large reduction in the sulfate burden on a global scale (-11 %), resulting in an increase of ~10 % (~20-40 %) in the PD 100-year global warming potential of CH_4 when chemistry-aerosol interactions and ari (ari and aci) were considered. Kurten et al. (2011) reported a global mean decrease in CDNC of 18 %, reduced cloudiness, and a strong positive aerosol forcing (2.32 W m⁻²) in a scenario in which they applied a 10-fold increase in CH_4 , the bulk of which was due to aerosol indirect effects (2.06 W m⁻²). More recently, Karset et al. (2018) found that the magnitude of the PD aerosol forcing reduced by 19 % (-1.32 to -1.07 W m⁻²) when the PI control simulation included PI oxidants rather than PD oxidants. The different oxidants cause greater condensate production relative to the amount of aerosol formed via nucleation, resulting in a shift in the aerosol size distribution towards larger particles, leading to cloud brightening in the PI atmosphere. The findings here are qualitatively consistent with these previous studies. However, there is disagreement on the extent to which the aerosol forcing is due to ari and/or aci, which warrants further investigation.

The inclusion of chemistry-aerosol interactions with aerosol-cloud interactions leads to a positive CRE in the PD CH₄ ERF from UKESM1. Although other models have a positive cloud adjustment associated with CH₄ in the AerChemMIP models (Thornhill et al., 2021b), it was not clear why the cloud adjustments varied in both sign and magnitude. This study, however, provides a process-based understanding of what is driving the positive CRE in UKESM1 and confirms that it is a combination of microphysical aerosol-cloud interactions and thermodynamics adjustments. The microphysical impacts occur due to CH₄-driven changes in oxidants in UKESM1 that alter cloud activation and reflectivity, leading to a contribution to the CRE of 0.28-0.30 W m⁻². Although defined differently, this is consistent with the positive UKESM1 cloud adjustment from Thornhill et al. (2021b). The thermodynamic effects are related to the radiative heating and stabilization of the upper troposphere, which on the whole reduced cloud cover and convection. This led to a negative CRE of -0.12 W m⁻² due to a dominant negative LW CRE of -0.35 W m⁻² and a positive SW CRE of 0.23 W m⁻². Overall, this means a CH₄-driven net CRE of 0.12 W m⁻². The cloud effects and other non-cloud forcing components added in a reasonably linear manner in our series of experiments, confirming that the

assumption of linearity in radiative kernel analysis is valid.

If the contribution of aci to the CRE was robust across models, the results would have wider implications for the role of CH₄ in historical and future climate and/or future climate mitigation. For example, future climate forcing and the Earth System response to continuing increases in anthropogenic emissions of CH₄ (e.g., Saunois et al., 2020; Jackson et al., 2020) and/or from feedbacks on natural CH₄ emissions (e.g., O'Connor et al., 2010; Dean et al., 2018; Gedney et al., 2019) would be greater than realised to date. CH₄ mitigation and CH₄ removal may be even more effective in reducing the total anthropogenic forcing on the Earth's radiative balance and the near-term climate response (e.g., Allen et al., 2021; Abernethy et al., 2021). However, the multi-model assessment of Thornhill et al. (2021b) suggests that the cloud adjustment in UKESM1 is anomalously large with respect to the other AerChemMIP models. A number of factors could be driving this: (1) an anomalous CH₄-driven oxidant response in UKESM1, (2) the lack of alternative nucleation mechanisms in UKESM1, such as boundary layer nucleation, and/or (3) the cloud response to aerosols in UKESM1 being too strong.

In relation to the oxidant response, the CH₄-OH feedback factor (Fiore et al., 2009) from UKESM1 appears to be consistent with other models (Thornhill et al., 2021b), suggesting that the OH response, at least, is reasonable. In relation to nucleation, Gordan et al. (2016) demonstrated how the inclusion of organicmediated boundary layer nucleation could weaken the aerosol forcing by nearly 30 % by increasing the CDNC in the PI atmosphere to a greater extent than in the PD period. While boundary layer nucleation is not included in the UKESM1 simulations here, it has been found to improve model biases in PD aerosol number concentrations (Ranjithkumar et al. 2021). For the cloud response to aerosols, Malavelle et al. (2017) showed that aci seem to be more realistic in the HadGEM3 model (i.e., in the physical model underpinning UKESM1) than in other models by evaluating the response to a large volcanic perturbation using observations of cloud properties. However, McCoy et al. (2020) show that the PD-PI change in CDNC is inconsistent with observational proxies as well as being outside of the range of AeroCom models. This could be due to CDNC being too high in the northern hemisphere in response to anthropogenic aerosol emissions or insufficient representation of background natural aerosol, including a lack of representation of boundary layer nucleation.

Nevertheless, these results indicate the importance of including interactive chemistry (and chemistry-aerosolcloud interactions) in ESMs when quantifying PD climate forcing. Such interactions are relevant to forcings from gas-phase constituents (O'Connor et al., 2021) as well as from the aerosol phase (Karset et al., 2018). The study also suggests that rapid adjustments included in the ERF framework should include chemical as well as physical adjustments to fully account for ES interactions. This is consistent with a recent assessment by Ramaswamy et al. (2019) who concluded that the radiative forcing concept is simple but needs to increasingly account for complex ES processes.

Acknowledgments

The development of the UK's Earth System Model, UKESM1, was funded by the Met Office Hadley Centre Climate Programme funded by BEIS and Defra (GA01101) and by the National Environmental Research Council (NERC) national capability grant for the UK Earth System Modelling project, grant number NE/N017951/1. FMO'C, TA, BTJ, and JPM were funded by the Met Office Hadley Centre Climate Programme funded by BEIS and Defra (GA01101). FMO'C also acknowledges the EU Horizon 2020 Research Programme CRESCENDO (grant agreement number 641816) and ESM2025 (grant agreement number 101003536) projects.

Table 1. List of all the atmosphere-only simulations carried out with UKESM1 to diagnose the apportionment of the pre-industrial (PI; Year 1850) to present-day (PD; Year 2014) effective radiative forcing (ERF) from methane (CH₄) using the "Elimination Method" and the "Single Forcing Method". *Only those simulations labelled Elimination Method Pair #1 are official AerChemMIP experiments. The table also includes the unique Simulation Identifier for each experiment.

Table 2. Effective radiative forcing (ERF) and its clear-sky (CS) and cloud radiative effect (CRE) components in the longwave (LW) and shortwave (SW) based on Eqn. (6) and including an estimate of the standard error, calculated at the present day (PD; Year 2014) relative to the pre-industrial period (PI; Year 1850) from a PI-to-PD methane (CH₄) perturbation in concentration using the "Elimination Method" pairs in Table 1. ERFs for individual forcing agents and/or interactions are inferred by differencing the ERF between two successive "Elimination Method" pairs.

Table 5: Aerosol and gas-phase budget terms for dimethyl sulphide (DMS), sulfur dioxide (SO₂), sulfate (SO₄) aerosol, and organic matter (OM) in UKESM1, based on the latter 30 years of the *piClim-control* 

and *piClim-CH*⁴ simulations. Units of production and loss are in Tg (S) yr⁻¹ for the sulfur species and in units of Tg (OM) yr⁻¹ for OM, where the ratio of carbon to OM is 1.0:1.4. Units of burden are in Tg (S) or Tg (OM) and the lifetime is in days. Of the aqueous-phase SO₂ oxidation fluxes, 25 % of the SO₂ is assumed to re-evaporate from the aqueous phase into the atmosphere and does not form SO₄ aerosol.

Experiment	Prescribed $CH_4$	Total CH ₄	Equilibrium $CH_4$	$[?]CH_4 / ppb$	Direct [?]CH ₄ RF / W m ⁻²
piClim- $control$	concn. / ppb 808	lifetime / years 8.1	concn. / ppb N/A	N/A	N/A

piClim-VOC	808	9.0	928	120	0.08
piClim-CH4	1831	9.8	2364	533	0.22

Table 6. Table indicating prescribed global mean  $CH_4$  concentrations, total  $CH_4$  lifetime, equilibrium  $CH_4$  concentrations and the additional RF contributions from the *piClim-NOx*, *piClim-VOC*, and *piClim-CH4* simulations to the emissions-based estimate of the direct  $CH_4$  RF at the PD (Year 2014) relative to PI (Year 1850).

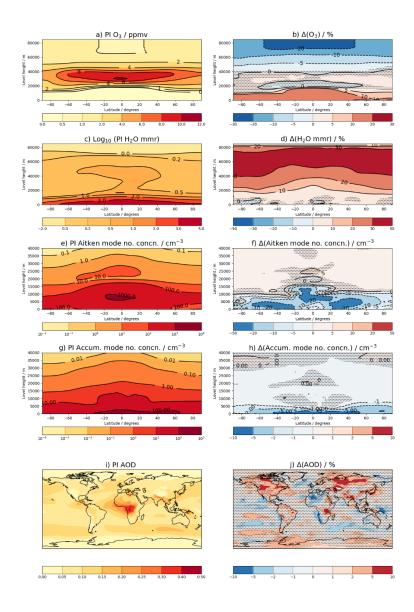

Figure 1. Multi-annual zonal mean distributions of a)  $O_3$ , c) WV, e) Aitken mode aerosol number concentration, g) Accumulation mode aerosol number concentration, and multi-annual global distribution of i) aerosol optical depth (AOD) in the pre-industrial (PI; Year 1850) period. The relative changes in  $O_3$ , WV and AOD due to the increase in CH₄ concentration between the PI and the present day (PD; Year 2014) are shown in b), d), and j), respectively, while the absolute changes in Aitken and Accumulation mode aerosol number concentrations are shown in f) and h), respectively. Stippled areas show where the differences are not statistically significant at the 95 % confidence interval.

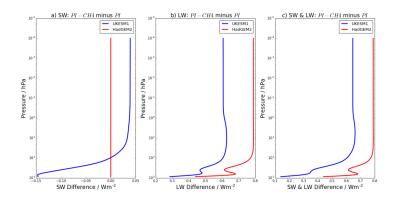

Figure 2. Comparison between two test cases (PI and PI-CH4) using the stand-alone SOCRATES radiation scheme with spectral data from HadGEM2 and UKESM1. Differences in the net outgoing radiative fluxes are shown for the shortwave (SW) in a), longwave (LW) in b), and SW&LW combined in c), using the sign convention that incoming radiative fluxes are positive and outgoing fluxes are negative.

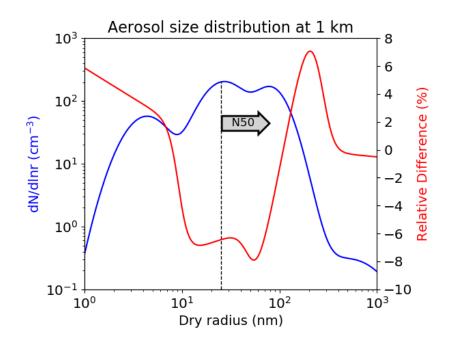

Figure 3: Global annual mean aerosol size distribution at 1 km in altitude in the PI atmosphere (blue; left axis) and the relative difference in the size distribution due to the PI-to-PD perturbation in  $CH_4$  (red; right axis), based on the latter 30 years of the 45-year long simulations. A vertical line marks those particles that are large enough to contribute to N50 in the PI atmosphere.

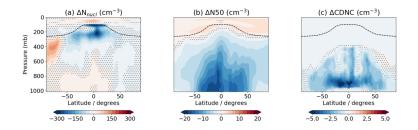

Figure 4. Multi-annual zonal mean changes in aerosol number concentrations, driven by the PI-to-PD change in  $CH_4$  concentration in the *piClim-CH4* simulation. Results include changes to (a) nucleation-mode particles, (b) number of particles greater than 50 nm in diameter, and (c) number of particles activated into cloud condensation nuclei. Stippled areas show where the differences are not statistically significant at the 95 % confidence interval.

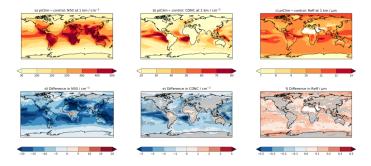

Figure 5. Global distributions of multi-annual mean a) N50, b) cloud droplet number concentration (CDNC) and c) cloud droplet effective radius (Reff) at 1km height and differences as a result of the PI-to-PD perturbation in CH₄ in d), e), and f). Units are in cm⁻³ for N50 and CDNC and in  $\mu$ m for Reff.

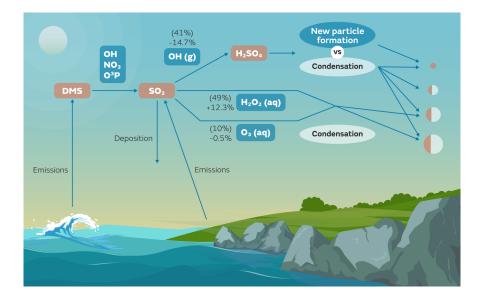

Figure 6: Schematic showing the mechanism for aerosol forcing attributable to methane at the present-day (PD; Year 2014) relative to the pre-industrial (PI; Year 1850). The relative contributions of the different oxidation pathways of sulfur dioxide (SO₂) lead to a change in the aerosol size distribution. Sulfur species include dimethyl sulfide (DMS) and sulfuric acid (H₂SO₄). Oxidants include hydroxyl (OH), nitrate (NO₃), atomic oxygen (O³P), hydrogen peroxide (H₂O₂) and ozone (O₃). The numbers in parentheses indicate the percentage of the total SO₂ oxidation that is oxidised through a particular pathway and the percentage below is the relative change in SO₂ oxidation as a result of the increase in methane (CH₄) concentration from PI to PD levels.

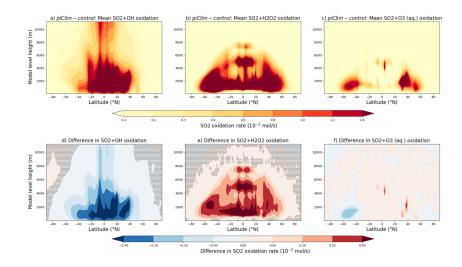

Figure 7: Multi-annual zonal mean distributions of sulfur dioxide  $(SO_2)$  oxidation fluxes via a) hydroxyl (OH), b) hydrogen peroxide  $(H_2O_2)$ , and c) ozone  $(O_3)$  in *piClim-control*. The difference in the oxidation rates as a result of the PI-to-PD methane increase is shown in d), e), and f). Units are in  $10^{-2}$  moles (S) per second.

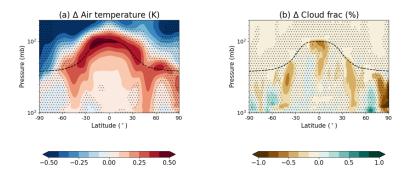

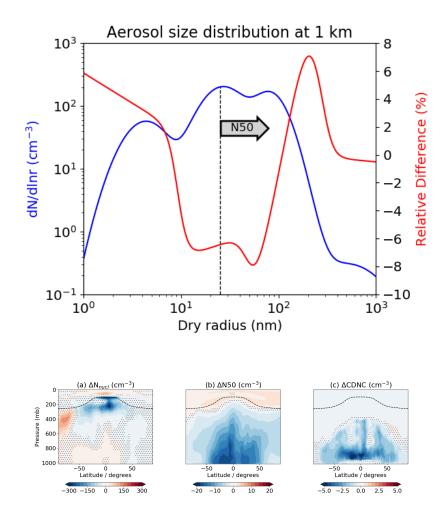

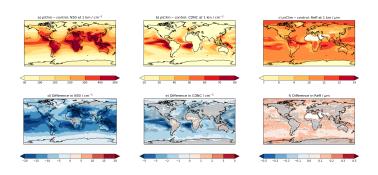

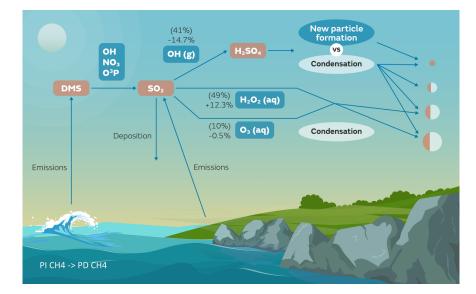

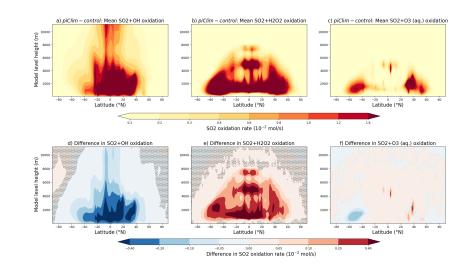

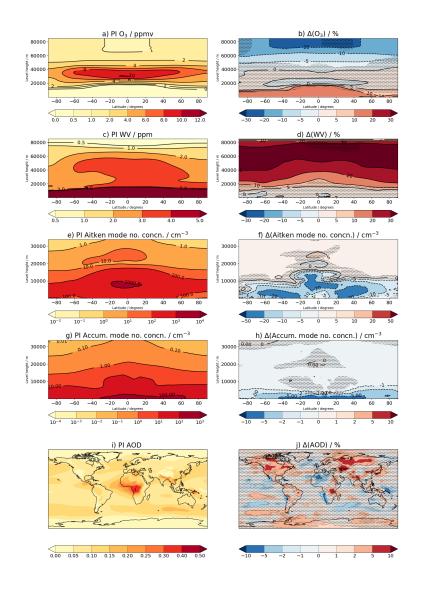

Figure 8. Multi-annual mean zonal mean changes in (a) temperature, (b) cloud fraction from the large-scale stratiform cloud scheme based on the difference between piClim-CH4 and piClim-control, where aerosol-cloud interactions were suppressed.

Key Points:

- The direct radiative effect of methane in UKESM1 is consistent with lineby-line radiative transfer calculations
- The total methane effective radiative forcing in UKESM1 includes an aerosol-mediated cloud forcing due to changes in cloud activation.
- The effective radiative forcing also includes a dynamically-driven cloud forcing from tropospheric warming and a reduction in cloud fraction.

•

#### Abstract

The pre-industrial (Year 1850) to present-day (Year 2014) increase in methane from 808 to 1831 ppb leads to a global mean effective radiative forcing (ERF) of 0.97  $\pm$  0.04 W m  $^{\text{-2}}$  in the United Kingdom's Earth System Model, UKESM1. The direct methane contribution is  $0.54 \pm 0.04$  W m⁻². It is better represented in UKESM1 than in its predecessor model HadGEM2 due to (i) the inclusion of absorption in the shortwave, (ii) updates to the spectral properties in the longwave, and (iii) the absence of an anomalous dust response in the UKESM1 simulations. An indirect ozone ERF of 0.13-0.20 W m⁻² is largely due to the radiative effect of the tropospheric ozone increase outweighing that of the stratospheric ozone decrease. An indirect water vapor ERF of  $0.07\pm0.05/0.02\pm0.04~{\rm W}~{\rm m}^{-2}$  is consistent with previous estimates based on the stratospherically-adjusted radiative forcing metric. The methane increase also leads to a cloud radiative effect of  $0.12 \pm 0.02$  W m⁻² from aerosol-cloud interactions and thermodynamic adjustments. The aerosol-mediated contribution  $(0.28 - 0.30 \text{ W m}^{-2})$  arises because methane-driven changes in oxidants alter the rate of new particle formation (-8 %), causing a change in the aerosol size distribution towards fewer but larger particles. There is a resulting decrease in cloud droplet number concentration and an increase in cloud droplet effective radius. There are additional shortwave and longwave contributions of 0.23 and -0.35 W m⁻² to the cloud forcing which are dynamically-driven. They arise from radiative heating and stabilization of the upper troposphere, resulting in a reduction in global cloud cover and convection. These results highlight the importance of chemistry-aerosol-cloud interactions and dynamical adjustments when quantifying climate forcing and can explain some of the diversity in multi-model estimates of methane forcing.

**Plain Language Summary** 

Methane is the second most important greenhouse gas after carbon dioxide. Methane is also chemically reactive in the atmosphere, and can cause changes in ozone, which is also a greenhouse gas. Methane can also affect the amount of water vapor in the atmosphere, where it too acts as a greenhouse gas. Aerosols, formed in the atmosphere through chemical processing, are also affected by methane. This study quantifies the impact of changes in methane concentration since the pre-industrial period on the Earth's energy budget at the present day and examines the impact from methane itself, as well as the impact from the additional methane-driven changes in ozone, water vapor, aerosols, and clouds. The biggest impact ( $\sim 55 \%$ ) is from methane itself, and of the remaining impact on the Earth's energy budget from methane, less than half is from ozone and clouds. The contribution from clouds is partly driven by changes in aerosol properties and partly driven by heating and a reduction in cloud cover. The impact from water vapor is small and is consistent with previous estimates. This study highlights the importance of including chemistry-aerosol-cloud interactions when quantifying the effect of pre-industrial to present-day changes in atmospheric constituents on climate.

# 1 Introduction

Methane  $(CH_4)$  is the second most important greenhouse gas (GHG) after carbon dioxide  $(CO_2)$  (Myhre et al., 2013). Due to its relatively short atmospheric lifetime of  $11.2 \pm 1.3$  yr (Prather et al., 2012) and its radiative efficiency being an order of magnitude larger than for  $CO_2$  (Ramaswamy et al., 2001; Myhre et al., 2013), CH₄ has an important role in mitigating near-term climate change (e.g., UNEP, 2011; Allen et al., 2018; Allen et al., 2021; Abernethy et al., 2021). However, future concentrations may be subject to climate feedbacks involving CH₄ natural sources (e.g., O'Connor et al., 2010; Dean et al., 2018; Gedney et al., 2019; Thornhill et al., 2021a; Kleinen et al., 2021). It is therefore important to quantify its climate forcing and relevant feedbacks for understanding the historical and future evolution of climate.

In relation to its climate forcing,  $CH_4$  has a direct radiative effect and indirect effects due to its reactivity. As well as being a tropospheric ozone (O₃) precursor,  $CH_4$  affects stratospheric O₃ (Pawson et al., 2014) and together, the O₃ changes lead to an indirect contribution to the total  $CH_4$  forcing.  $CH_4$  oxidation is also a major sink for the hydroxyl (OH) radical, and changes in  $CH_4$  lead to changes in O₃, OH, and other oxidants. These oxidants determine the rate of formation of secondary aerosol such as sulfate and secondary organic aerosol (SOA) (e.g., Kelly et al., 2018; Mulcahy et al., 2020), potentially giving rise to additional indirect aerosol forcings (e.g., Shindell et al., 2009; Karset et al., 2018) through aerosol-radiation interactions (ari) and/or aerosol-cloud interactions (aci), although these effects have not been well quantified to date.

Water vapor (WV) is also an important component of the radiative balance in the stratosphere (e.g., Forster and Shine, 1999). Trends in observed stratospheric WV could be due to increases in stratospheric  $CH_4$  oxidation (Hansen et al., 2005) or direct aircraft emissions (Wilcox et al., 2012). However, some of the observed increase can be attributed to a climate feedback (e.g., Dessler et al., 2013). Studies disagree on the relative role of  $CH_4$  (e.g., Oman et al., 2011; Hurst et al., 2011). Nevertheless, it is clear that indirect forcings through changes in  $O_3$ , stratospheric WV, and potentially aerosols, can significantly impact  $CH_4$  forcing (Hansen et al., 2005; Shindell et al., 2005; Shindell et al., 2009; Myhre et al., 2013; Winterstein et al., 2019; Thornhill et al., 2021b).

Recent studies that rank anthropogenic drivers of climate change make use of the effective radiative forcing (ERF) as the preferred metric of choice (e.g., Smith et al., 2018; Smith et al., 2020; O'Connor et al., 2021; Thornhill et al., 2021b) since it is more representative of the predicted global mean temperature response (Hansen et al., 2005; Richardson et al., 2019). It was defined in the Intergovernmental Panel on Climate change (IPCC) 5th assessment report (AR5; Myhre et al., 2013) at the top-of-atmosphere (TOA) as:

$$ERF = IRF + \sum_{i=1}^{n} A_i$$

where IRF is the TOA instantaneous radiative forcing from an imposed perturbation (e.g., a change in a GHG concentration) and  $A_i$  is a rapid atmospheric or land surface adjustment (e.g., atmospheric temperature, clouds, water vapour, albedo, etc.) that gives rise to additional positive or negative changes in the net TOA radiative fluxes. The ERF differs from the more traditional radiative forcing metric, in that the latter only includes a stratospheric temperature adjustment, whereas the ERF also includes tropospheric and land surface adjustments.

In the case of the direct radiative effect of  $CH_4$ , Smith et al. (2018) found that the present-day (PD)  $CH_4$  ERF is approximately equivalent to its IRF. The rapid adjustment associated with stratospheric temperature is negligible and the other adjustments (e.g., tropospheric temperature and water vapor) are small, have opposing signs, and roughly sum to zero. However, as indicated above, there are additional Earth System (ES) interactions or chemical adjustments that affect the net TOA radiative fluxes when  $CH_4$  is considered within a full ES context (e.g., Hansen et al., 2005; Shindell et al., 2005; Shindell et al., 2009; Winterstein et al., 2019). Therefore, when quantifying the climate forcing of  $CH_4$ , ES interactions or chemical adjustments need to be fully considered (Shindell et al., 2009; Myhre et al., 2013) in addition to physical adjustments (Smith et al., 2018).

A recent study by Thornhill et al. (2021b) quantified a range of PD anthropogenic ERFs and considered both physical and chemical adjustments using an ensemble of models that participated in the Aerosol and Chemistry Model Intercomparison Project (AerChemMIP; Collins et al., 2017). The multi-model PD CH₄ ERF was 0.67  $\pm$  0.17 W m⁻². Some of the model spread is due to differing complexities in the representation of chemistry in the respective models (and hence differences in their indirect contributions, e.g., from O₃). However, some

of the model diversity is due to differences in the sign and magnitude of the cloud adjustment (-0.06 to 0.24 W m⁻²). Although other AerChemMIP models show a positive cloud adjustment (e.g., GISS-E2-1 (Bauer et al., 2020) and CESM-WACCM (Emmons et al., 2020)), the United Kingdom's Earth System Model, UKESM1 (Sellar et al., 2019), has the strongest positive cloud adjustment of the AerChemMIP models. This results in UKESM1 being one of only two models (including CESM-WACCM) to have a positive tropospheric adjustment overall and the highest PD CH₄ ERF of 0.97 ± 0.04 W m⁻² (O'Connor et al., 2021) of the multi-model ensemble.

In the Thornhill et al. (2021b) study, radiative kernels (Chung and Soden, 2015; Smith et al., 2018; Smith et al., 2020) and diagnostic radiation calls (Ghan, 2013) enabled a breakdown of the total  $CH_4$  ERF into different constituents (gas phase versus aerosol phase). However, it is unclear whether the relevant adjustments are additive when more than one forcing agent is perturbed (as is the case for  $CH_4$  in an ES context). The kernel approach also cannot distinguish between cloud adjustments that are dynamically driven and those that are due to changes in aerosol-mediated cloud nucleation (Thornhill et al., 2021b). As a result, a complete process-based understanding of the UKESM1 total  $CH_4$  ERF and the AerChemMIP multi-model diversity in the PD  $CH_4$  ERF is lacking.

The aim of the current study is thus to apportion the UKESM1 PD  $CH_4$  forcing quantified in O'Connor et al. (2021) between the direct  $CH_4$  contribution and indirect contributions using the widely-adopted metric of choice for forcing, i.e., ERF, thereby including physical and chemical rapid adjustments. This study will also aim to test whether the relevant contributions (including adjustments) are additive and provide a process-based understanding of the positive cloud adjustment in UKESM1. Although  $CH_4$  can affect the lifetime of other GHGs such as chlorofluorocarbons (Boucher et al., 2009) or nitrous oxide (Hsu and Prather, 2010), they are concentration-driven in UKESM1 and their response to  $CH_4$  is therefore constrained. As a result, the focus here will be on the direct  $CH_4$  ERF from the change in  $CH_4$  concentration between the pre-industrial (PI) period and the PD, and the corresponding indirect ERFs from  $CH_4$ -driven changes in  $O_3$ , stratospheric WV, and potentially aerosols. The paper is organised as follows. Section 2 gives a brief description of the UK's Earth System Model (UKESM1) and the experimental design used in this study. Results can be found in Sect. 3 while conclusions can be found in Sect. 4.

# 2 Model Description and Experimental Design

The model used in this study is the atmospheric and land components of the UK's Earth System Model, UKESM1 (Sellar et al., 2019). It has a resolution of N96L85, equivalent to a horizontal resolution of approximately 135 km, with 85 hybrid height levels covering an altitude range from the surface up to the model lid at 85 km. The model includes a troposphere-stratosphere chemistry scheme (Archibald et al., 2020) from the United Kingdom Chemistry and Aerosol (UKCA) model (Morgenstern et al., 2009; O'Connor et al., 2014) coupled to a two-moment aerosol scheme called GLOMAP-mode (Mann et al., 2010;

Mulcahy et al., 2018; Mulcahy et al., 2020). A full description and evaluation of the gas-phase chemistry and aerosol schemes in UKESM1 can be found in Archibald et al. (2020) and Mulcahy et al. (2020), respectively.

Here, UKESM1 is run in an atmosphere-only configuration, using sea surface temperatures, sea ice conditions, surface water dimethyl sulphide and chlorophyll concentrations, vegetation distribution, leaf area index, and canopy heights representative of a pre-industrial (PI; Year 1850) state. These climatologies, including a seasonal cycle, were calculated using 30 years output from the coupled (atmosphere-ocean) PI control experiment of UKESM1 (*piControl*), characterised in Sellar et al. (2019) and run as part of the 6th Coupled Model Intercomparison Project (CMIP6; Eyring et al., 2016).

The experiments conducted here consist of paired simulations: a PI (Year 1850) timeslice simulation and a parallel simulation, in which the global mean  $CH_4$ concentration prescribed as a lower boundary condition in the model is changed from its Year-1850 value (808 ppb) to its present-day (PD; Year 2014) value (1831 ppb) based on CMIP6 recommendations from Meinhausen et al. (2017).  $CH_4$  concentrations aloft are simulated interactively by the model. The initial pair follows the protocol from the Aerosol and Chemistry Model Intercomparison Project (AerChemMIP; Collins et al., 2017) and are called *piClim-control* and *piClim-CH4*, respectively. All other model settings in the experiments are representative of the PI period using CMIP6 recommendations. Briefly here, other GHG concentrations are prescribed according to Meinhausen et al. (2017). Gas-phase and aerosol-phase anthropogenic and biomass burning emissions for the PI period are taken from Hoesly et al. (2018) and van Marle et al. (2017), respectively. Natural volcanic and solar forcings were fixed in all simulations at Year-1850 levels (Arfeuille et al., 2014; Thomason et al., 2018; Matthes et al., 2017) using those specified for CMIP6 (Eyring et al., 2016). Further details are provided in O'Connor et al. (2021)

The apportionment of the total  $CH_4$  ERF between direct and indirect ERFs is calculated in two ways. The first approach is called the "Elimination Method", whereby additional pairs of simulations incrementally disable an interaction or forcing agent from influencing the TOA radiative fluxes, until the last pair only allows  $CH_4$  itself to affect the TOA, thereby giving the direct  $CH_4$  ERF. The difference between successive pairs is then used to infer the proportion of the total  $CH_4$  ERF to that particular indirect effect, forcing agent or interaction assuming linearity.

As mentioned, the final pair above gives the direct  $CH_4$  ERF. Similarly, other paired experiments are conducted, such that the ERF associated with a single composition change or interaction is calculated directly rather than inferring it from differencing two pairs. This methodology is referred to as the "Single Forcing Method" and gives rise to smaller errors than the "Elimination Method". All the experiment pairs carried out for this study using the two methods are listed in Table 1 and were run for 45 years, with the latter 30 years used for analysis. The ERF itself is calculated from the difference in the TOA radiative fluxes between a perturbation experiment (e.g.,  $piClim-CH_4$ ) and its control experiment (e.g., piClim-control) as follows:

$$ERF = \Delta F$$
, (1)

where F includes the IRF as well as other changes to the TOA radiative fluxes due to rapid adjustments. Although strictly by definition, the ERF should exclude land surface temperature adjustments, model experimental protocols and recommendations for quantifying ERFs to date (e.g., Forster et al., 2016; Pincus et al., 2016; Collins et al., 2017) fix sea surface and sea ice conditions only. Hence, the ERFs quantified here include a contribution from temperature adjustments over the land surface. However, this contribution was found to be small in the case of the CH₄ ERF – typically 0.02-0.03 W m⁻² (Thornhill et al., 2021b) but is much larger for CO₂ forcing (Andrews et al., 2021).

The ERF can be decomposed into the clear-sky component (ERFcs) and the change in the cloud radiative effect ( $\Delta CRE$ ) as follows:

$$ERF = \Delta Fcs + \Delta (F - Fcs) (2)$$
$$= ERFcs + \Delta CRE, (3)$$

where Fcs is the clear-sky (CS) radiative flux. Due to the potential of the  $CH_4$  perturbation to alter atmospheric oxidants and secondary aerosols in UKESM1 leading to "cloud masking" (e.g., Zelinka et al., 2014),  $\Delta CRE$  is diagnosed from "clean" radiation calls that exclude aerosol-radiation interactions (ari), as recommended in Ghan (2013):

$$ERF = \Delta(F - Fclean) + \Delta Fcs, clean + \Delta(Fclean - Fcs, clean) (4)$$
  

$$ERF = Aerosol \ IRF + ERFcs, clean + \Delta CRE' (5)$$
  

$$ERF = ERFcs' + \Delta CRE'. (6)$$

The ERF is, thus, separated into a component due to cloud property changes  $(\Delta CRE')$  and the non-cloud forcing (ERFcs'). Here, ERFcs' is the sum of the aerosol IRF and any non-aerosol changes in CS fluxes (due to CH₄, O₃, etc.) and differs slightly from ERFcs in Eqn. (3), in that it can include the impact of aerosol scattering and absorption in the clear-air above or below clouds. This is the approach adopted by O'Connor et al. (2021) in quantifying a wide range of PD anthropogenic ERFs in UKESM1. However, it is worth noting that  $\Delta CRE'$ , as defined here, differs from the cloud adjustment in Thornhill et al. (2021b). In that study, the cloud adjustment is estimated from  $\Delta CRE'$  but corrects for cloud masking using kernel-derived non-cloud adjustments and the non-aerosol IRF.

For each pair in Table 1, the ERF is calculated as the time-mean global-mean difference in the TOA radiative fluxes, using the latter 30 years of the 45-year long simulations and decomposed into its components following Eqn. (6) and O'Connor et al. (2021). In addition to the "Elimination Method" and "Single

Forcing Method" simulation pairs (Table 1), the TOA IRF from the  $CH_4$ -driven changes in aerosols was diagnosed through a double call to the radiation scheme (Ghan et al., 2012) in order to quantify the contribution of the aerosol IRF to *ERFcs*' in Eqn. (6). ERF estimates and their components from the different methods can be found in Tables 2 and 3 and will be discussed in Sect. 3.

The UKESM1 simulations conducted here (Table 1) were also complemented with offline calculations using the ESM's radiation scheme SOCRATES (Suite of Community Radiation Codes based on Edwards and Slingo, 1996). The offline SOCRATES experimental setup followed the PI aerosol- and cloud-free protocol from the Radiative Forcing Model Intercomparison Project (RFMIP; Pincus et al., 2016), designed to test the accuracy of clear-sky radiative transfer parameterizations on global scales. The setup consists of 100 profiles of PI atmospheric conditions including GHG concentrations (called PI here), that when weighted appropriately and averaged, approximate to global annual mean PI radiative fluxes. A parallel perturbation setup consists of an atmosphere, in which all conditions remain at PI levels except for a PI-to-PD perturbation in CH₄ concentration (called PI-CH₄). Together, PI and PI-CH₄ are representative of the UKESM1 simulations piClim-control and piClim-CH4, respectively, and the difference in radiative fluxes gives the direct  $CH_4$  IRF. A second perturbation setup is representative of a PI atmosphere, but the only perturbation applied is the  $CH_4$ -driven  $O_3$  change diagnosed from UKESM1 (called *PI-O3*). Together, PI and PI-O3 mimic the Single Forcing Method #3 pair of UKESM1 simulations (Table 1) and the difference in radiative fluxes yields the indirect O₃ IRF. In a similar way, the indirect WV IRF can be diagnosed by quantifying the difference in radiative fluxes between PI and PI-WV, where PI-WV is representative of a PI atmosphere but with the UKESM1  $CH_4$ -driven change in WV diagnosed applied.

#### 3 Results

The total PD (Year 2014) CH₄ ERF relative to the PI (Year 1850) period is  $0.97 \pm 0.04$  W m⁻² (O'Connor et al., 2021; Table 2), where the 0.04 W m⁻² is the standard error following Forster et al. (2016). Previous studies have found that CH₄ forcing is almost double that of the direct CH₄ forcing (Shindell et al., 2005; Myhre et al., 2013). This is also evident here, with the direct CH₄ ERF estimated to be half (0.54 ± 0.04 W m⁻²; Table 2) that of the total CH₄ ERF due to indirect effects. These indirect effects result from changes in O₃, stratospheric WV, and potentially aerosols. Tables 2 and 3 provide the indirect ERFs from O₃ and WV; estimates from the two methods agree to within their error bars:  $0.13 \pm 0.05$  W m⁻² from the Elimination Method and  $0.20 \pm 0.04$  W m⁻² from the Single-Forcing Method for O₃ and  $0.07 \pm 0.05$  W m⁻²/0.02 ± 0.04 W m⁻² for WV.

The ERF estimates also suggest that the total  $CH_4$  ERF from UKESM1 includes a significant indirect contribution from aerosols, particularly aerosolcloud interactions (aci). As was the case for  $O_3$  and WV, the indirect ERFs from the two methods agree to within their error bars for both aci  $(0.28 \pm 0.06 \text{ W m}^{-2} \text{ from the Elimination Method and } 0.30 \pm 0.04 \text{ W m}^{-2} \text{ from the Single Forcing Method; Tables 2 and 3) and aerosol-radiation interactions (ari) (-0.05 \pm 0.06 \text{ W m}^{-2}/0.00 \pm 0.04 \text{ W m}^{-2})$ . The results also indicate that the direct and indirect ERFs are additive and that they add up linearly. For example, the total CH₄ ERF (0.97 ± 0.04 W m⁻²; Table 2) closely matches the sum of the individual direct and indirect ERFs (1.06 ± 0.09 W m⁻²; Table 3).

Apportionment of the forcing using the Elimination and Single-Forcing pairs in this way may help to explain some of the spread in PD  $CH_4$  ERF estimates from the AerChemMIP multi-model ensemble (Thornhill et al., 2021b) and provide a process-based understanding of the positive cloud adjustment in UKESM1. The direct  $CH_4$  ERF and the indirect ERFs from  $O_3$ , WV, and aerosols in UKESM1 and the relevant changes in composition are discussed further in the following sections.

### 3.1 Composition Changes

Figure 1 shows multi-annual mean pre-industrial (*piClim-control*) distributions of O₃, WV, Aitken and accumulation mode aerosol number concentrations, and aerosol optical depth (AOD), as well as changes due to the PI-to-PD increase in  $CH_4$  concentration (*piClim-CH*4 minus *piClim-control*). It shows that in the PI atmosphere,  $O_3$  concentrations show a maximum in the tropical stratosphere of greater than 10 ppmv, with minimum concentrations aloft and in the troposphere (Figure 1a). As a tropospheric  $O_3$  precursor, the  $CH_4$  increase gives rise to an increase in tropospheric  $\mathrm{O}_3$  concentrations of 10-20 % on a zonal annual mean basis (Figure 1b). Reductions of 0-10 % in stratospheric O₃ concentrations also occur, reflecting the complex interactions between  $CH_4$  and stratospheric  $O_3$  due to both the direct impact of  $CH_4$  on the odd hydrogen (HOx) loss cycle (Pawson et al., 2014) and the indirect impact of  $CH_4$ -induced increases in stratospheric WV (e.g., Stenke and Grewe, 2005). This reduction is lower than the 15 % reduction in  $\mathrm{O}_3$  following a 2-fold increase from PD  $CH_4$  concentrations in Winterstein et al. (2019) although their simulations had PD chlorine loading. They also showed increases in WV of up to 50 % in the middle and higher stratosphere. Here, the  $CH_4$  perturbation represents more than a doubling of the global mean PI concentration and we find maximum increases in WV of over 30 % (Figure 1d). The  $CH_4$  perturbation also gives rise to changes in other oxidants (e.g., OH), causing the total  $CH_4$  lifetime to increase from 8.1 years in piClim-control to 9.8 years in piClim-CH4 (O'Connor et al., 2021). In turn, this change in oxidants leads to a change in the global distribution of AOD. In particular, the low background aerosol loading in the PI atmosphere, which has implications for PD anthropogenic aerosol forcing (Carslaw et al., 2013), sees some regional increases and decreases of over 5 % in magnitude (Figure 1j). Indeed, Shindell et al. (2009) found an aerosol forcing attributable to a PI-to-PD change in  $CH_4$  although in that study, a change in sulfate burden on a global scale was more evident (-11 %). Here, the global mean AOD changes by less than 2 %; the regional changes are limited in spatial extent and statistical significance, and have opposing signs.

However, statistically significant differences are more evident in the aerosol size distribution. For example, PI Aitken mode number concentrations peak at more than 1000 cm⁻³ in the tropical mid-troposphere (Figure 1e). The PI-to-PD  $CH_4$  concentration perturbation leads to reductions in Aitken mode number concentrations throughout the troposphere, with a maximum reduction of up to 50 cm⁻³ (Figure 1f). Likewise, accumulation mode number concentrations peak near the surface in the tropics and the northern hemisphere mid-latitudes in the PI period (Figure 1g), with values of over 100 cm⁻³ and reductions of up to  $10 \text{ cm}^{-3}$  resulting from the CH₄ perturbation (Figure 1h). Given the weak and limited spatial extent of the changes in AOD, these reductions in Aitken and accumulation mode number concentrations are commensurate with increases in coarse mode number concentration (not shown). These results support the findings that the indirect contribution to the total PD  $CH_4$  ERF from aerosolradiation interactions (ari) in UKESM1 is small (Tables 2 and 3) and that the CH₄-driven change in the aerosol size distribution has the potential to contribute significantly to the  $CH_4$  ERF through aerosol-cloud interactions (aci; Tables 2 and 3). This is explored further in Sect. 3.4.

## 3.2 Direct Methane Effective Radiative Forcing (ERF)

The direct  $\rm CH_4~ERF$  at the PD relative to the PI period is 0.54  $\pm$  0.04 W m^-2 (Tables 2, 3), consistent with the traditional stratospherically-adjusted radiative forcing (SARF) estimate from the updated expression from Etminan et al. (2016) i.e., 0.56 W m⁻². As was the case for the total  $CH_4$  ERF (Table 2), the majority of this forcing is in the clear sky (CS) longwave (LW) component  $(0.60 \pm 0.02 \text{ W m}^{-2})$ , with the CS shortwave (SW) contribution to the ERF  $(0.07 \pm 0.02 \text{ W m}^{-2})$  being more than offset by the cloud radiative effect (CRE)  $(-0.14 \pm 0.04 \text{ W m}^{-2})$ . The negative CRE in the direct CH₄ ERF from UKESM1 is consistent with Smith et al. (2018). In that study, only those models that included SW absorption by  $CH_4$  had a negative cloud adjustment; the SW absorption causes tropospheric heating and reductions in upper tropospheric cloud amounts. However, in comparing with the direct  $CH_4$  ERF from the HadGEM2 model (Collins et al., 2011) from Andrews (2014) in Table 4, there is good quantitative agreement between the net CS (0.68  $\pm$  0.03 cf. 0.61 W m⁻²) and the net CRE (-0.14  $\pm$  0.04 cf. -0.11 W m⁻²) components. However, there is poor agreement with the individual CS SW (0.07  $\pm$  0.02 cf. -0.13 W m⁻²) and LW  $(0.60 \pm 0.02$  cf. 0.74 W m⁻²) components, which cannot be reconciled by the different years representing the PI and PD in the two studies. Indeed, UKESM1 shows a positive CS forcing in the SW consistent with Etminan et al. (2016)whereas HadGEM2 has a non-zero CS forcing despite no treatment of solar absorption by CH₄. HadGEM2 also shows a larger CS LW forcing than UKESM1, which could be related to the lack of treatment of  $CH_4$  in the SW (Collins et al., 2006; Li et al., 2010; Etminan et al., 2016). However, the anomalous negative CS SW component in the HadGEM2 simulations offsets its stronger positive CS LW component, resulting in the two models having comparable net CS components for the direct  $CH_4$  ERF.

To investigate the differences between HadGEM2 and UKESM1 further, we make use of the study by Smith et al. (2018) which found that the direct  $CH_4$  ERF is approximately equal to its instantaneous radiative forcing (IRF), due to the rapid adjustments included in the ERF either being small or summing to zero. As a result, the idealised stand-alone PI test case from the RFMIP protocol (Pincus et al., 2016) can be used here to investigate the differences in the direct  $CH_4$  ERF CS components between HadGEM2 and UKESM1.

As outlined in Sec. 2, the main test case used from RFMIP is that of a cloudfree aerosol-free PI atmosphere - referred to here as PI. A parallel perturbation test case (*PI-CH4*) with the PI-to-PD perturbation applied was set up, with both test cases run using the corresponding spectral data files from HadGEM2 and UKESM1. Figure 2 shows profiles of the differences in the SW, LW and net outgoing radiative fluxes between the two test cases (PI-CH4 minus PI). It shows that with the HadGEM2 spectral data, the SW IRF at TOA under aerosol-free cloud-free conditions is expected to be zero. It also shows that the small positive CS SW ERF from the UKESM1 simulation is consistent with the SW IRF at TOA calculated offline. Looking at the LW fluxes, the difference in the CS LW ERF between HadGEM2 and UKESM1 is mostly explained by the updated spectroscopic data used in UKESM1 relative to HadGEM2 (Walters et al., 2019), although some discrepancy (~0.06 W m⁻²) still remains. A sensitivity test with offline SOCRATES using 3D  $CH_4$  fields from UKESM1 rather than constant  $CH_4$  concentrations throughout the depth of the atmosphere, at most, accounts for only  $0.01 \text{ W m}^{-2}$ .

Although the stand-alone tests support the findings from UKESM1 in both the CS SW and LW components of the direct  $CH_4$  ERF, they do not explain the non-zero (or negative) CS SW forcing in HadGEM2. Further investigations into the HadGEM2 simulations show that the negative CS SW ERF was due to changes in dust outflow from North Africa; the 3  $CH_4$  perturbation experiments showed significant variability in the CS SW ERF i.e., -0.04 to -0.28 W m⁻², with the -0.13 W m⁻² reported in Andrews (2014) being the average of the 3 ensemble members. It is still unclear what mechanism is driving the dust response in HadGEM2 but dust production in that model was found to be highly sensitive to various atmospheric and surface variables (Collins et al., 2011). Nevertheless, the results indicate that the direct  $CH_4$  ERF is better represented in UKESM1 than in HadGEM2 and is more consistent with the Etminan et al. (2016) expression based on line-by-line radiative transfer calculations. UKESM1 is also more consistent with the multi-model mean of the IRF due to a PD-to-PI  $CH_4$ perturbation from present day in Pincus et al. (2020). This improvement in UKESM1 is three-fold: (i) the inclusion of SW absorption by  $CH_4$ , (ii) the update to the LW spectral data for CH₄, and (iii) the absence of an anomalous dust response in the UKESM1  $CH_4$  perturbation experiments.

# 3.3 Methane-Driven Ozone and Water Vapor ERFs

As seen from Figure 1, the PI-to-PD perturbation increases tropospheric  ${\rm O}_3$  and decreases stratospheric  ${\rm O}_3,$  changes which together contribute an indirect

 $O_3$  ERF to the total CH₄ ERF. Using the "Elimination Method" and "Single Forcing Method", we calculate an indirect  $O_3$  ERF attributable to the PI-to-PD change in CH₄ concentration of  $0.13 \pm 0.05$  and  $0.20 \pm 0.04$  W m⁻², respectively, showing good consistency between the two methods. This positive forcing is predominantly in the CS ( $0.18 \pm 0.04/0.24 \pm 0.03$  W m⁻²; Tables 2, 3) and in the LW ( $0.19 \pm 0.02/0.17 \pm 0.02$  W m⁻²; Tables 2, 3), reflecting the sensitivity of forcing per unit mass to the vertical distribution of  $O_3$  changes (Lacis et al., 1990) and the dominance of the tropospheric  $O_3$  change to the ERF (Skeie et al., 2020). There is a very weak CRE ( $-0.07 \pm 0.05/-0.04 \pm 0.04$  W m⁻²; Tables 2, 3) but given the standard errors, its contribution to the indirect  $O_3$  ERF and the total CH₄ ERF can be considered negligible. This is consistent with Skeie et al. (2020), who found that the cloud adjustment associated with  $O_3$  forcing is small (-0.02 W m⁻²), albeit opposite in sign to that found here.

It is also worth noting that water vapor (WV) production from  $CH_4$  oxidation was switched on when isolating the indirect  $O_3$  ERF using the "Elimination Method" (Table 1). This has the potential for the indirect  $O_3$  ERF to include the radiative effect of  $O_3$  changes resulting from  $CH_4$ -driven increases in stratospheric WV (e.g., Stenke and Grewe, 2005) in addition to the radiative effect of more direct  $CH_4$ -driven changes in tropospheric and stratospheric  $O_3$ . On the other hand, for the "Single Forcing Method", the  $O_3$  ERF was quantified with WV production from  $CH_4$  switched off. Hence, the smaller magnitude of the inferred  $O_3$  ERF compared with that from the Single Forcing method could be due to a difference in  $O_3$  in the model simulations from WV. However, the magnitude of the difference in the  $O_3$  change was less than 2 %, with regional differences of opposing sign; the resulting impact on the indirect  $O_3$  ERF can be considered negligible given the magnitude of the errors.

The study by O'Connor et al. (2021) found that the stratospherically-adjusted radiative forcing (SARF) from changes in tropospheric O₃ due to the PI-to-PD change in  $CH_4$  concentration is 0.14 W m⁻². Taking a whole-atmosphere perspective, we estimate a whole-atmosphere  $\mathrm{O}_3$  SARF attributable to the PIto-PD change in  $CH_4$  concentration of 0.15 W m⁻² by combining the  $O_3$  IRF calculated offline using SOCRATES  $(0.11 \text{ W m}^{-2})$  with the stratospheric temperature adjustment (0.04 W m⁻²) calculated using a temperature radiative kernel (Smith et al., 2018). This suggests that the contribution from the stratospheric  $O_3$  SARF is at most 0.01 W m⁻². It confirms that although the  $O_3$  reductions in the upper stratosphere are substantial (0-20 %), the global mean stratospheric changes contribute little to the indirect whole-atmosphere  $O_3$  SARF. This is as a result of  $O_3$  forcing being dominated by changes in the upper troposphere and lower stratosphere (UTLS) (Lacis et al., 1990; Skeie et al., 2020) and the lack of atmospheric mass aloft. However, potential increases in CH₄ beyond the PD may play a more significant role in stratospheric  $O_3$  forcing in the future as concentrations of ozone-depleting substances decrease (e.g., Iglesias-Suarez et al., 2018). In particular, including troposphere-stratosphere chemistry schemes into ESMs (e.g., Morgenstern et al., 2017) provides additional insight into climate change drivers and has greater relevance for policy makers (Shindell et al.,

# 2013).

In addition to  $O_3$ , water vapor (WV) is also an effective GHG close to the tropopause (Lacis et al., 1990; Forster and Shine, 2002) and thus WV production from  $CH_4$  oxidation has the potential to exert an indirect forcing. However, previous studies (e.g., Hansen et al., 2005; Myhre et al., 2007) have found the indirect stratospheric WV SARF to be small; AR5 concluded that it is in the range of 0.02 to 0.12 W m⁻² with a central estimate of 0.07 W m⁻² (Myhre et al., 2013). This is due to the change in WV close to the tropopause being small (Hansen et al., 2005). In this study, the change in the UTLS region is estimated to be less than 10 %. Larger changes in WV occur in the upper stratosphere but being optically thin and convectively stable, the changes there are less effective at influencing the radiative balance (Hansen et al., 2005). For comparison purposes, we quantify the WV SARF in two ways. Firstly, scaling the direct CH₄ SARF of 0.54 W m⁻² from Etminan et al. (2016) by 15 %, as done in the Intergovernmental Panel on Climate Change (IPCC) 4th assessment report (Forster et al., 2007), yields 0.08 W m⁻². Secondly, using the modeldiagnosed changes in WV and temperature yield a TOA IRF of 0.05 W m⁻² and a stratospheric temperature adjustment of 0.04 W m⁻² from offline SOCRATES and a radiative kernel (Smith et al., 2018), respectively, we estimate a UKESM1derived SARF of 0.09 W m⁻². Both estimates are consistent with the range from previous studies (Hansen et al., 2005; Myhre et al., 2007; Myhre et al., 2013). The indirect TOA ERFs quantified here by the "Elimination" and "Single Forcing" methods  $(0.07 \pm 0.05/0.02 \pm 0.04 \text{ W m}^{-2}; \text{ Tables 2, 3})$  are consistent with each other but in the case of the Single Forcing method, the estimate appears to be marginally weaker than the SARF estimates. This indicates that there may be rapid adjustments other than the stratospheric temperature adjustment and that forcing estimates may be sensitive to the choice of metric (e.g., Smith et al., 2018). Nevertheless, the stratospheric WV forcing here is weakly positive and the choice of forcing metric does not have a major impact on the understanding of the role of  $CH_4$ -driven changes in WV in the PD forcing of climate.

#### 3.4 Methane-Driven Aerosol ERF and Cloud Radiative Effect

A significant finding of this study is that increases in  $CH_4$  concentration lead to changes in aerosol properties resulting in a positive contribution to the total  $CH_4$  ERF. This aerosol-mediated term is estimated to be  $0.23 \pm 0.06$  or  $0.30 \pm 0.06$  W m⁻², depending on whether the "Elimination Method" or "Single Forcing Method" is used (Tables 2 and 3). This forcing is almost entirely from aerosol-cloud interactions (aci) and their influence on the SW radiative effects of clouds. The aci component is estimated to be  $0.28 \pm 0.06/0.30 \pm 0.04$  W m⁻² (Table 2, 3) and the aerosol-radiation interactions (ari) component is either weakly negative or neutral at  $-0.05 \pm 0.06/0.00 \pm 0.04$  W m⁻² (Table 2, 3). A double call to the radiation scheme following Ghan et al. (2012) confirms that the magnitude of the  $CH_4$ -driven aerosol IRF is less than 0.01 W m⁻², consistent with the near-zero ari term derived from the Elimination and Single-Forcing methods. This is also consistent with the global mean AOD change only being of the order of 2 % (Figure 1). The explanation for the relatively substantial aci component lies in more subtle changes to aerosol size distributions and number concentrations. These appear to have been triggered by changes in oxidation rates affecting secondary aerosol formation and the nucleation of new particles. These following sub-sections explore these processes in further detail.

# 3.4.1 Aerosol-cloud microphysical changes

As shown in Figure 1, the PI-to-PD increase in  $CH_4$  leads to statistically significant reductions in aerosol number concentrations, particularly across the Aitken mode, but also in the accumulation mode. This is also clear from examining the aerosol size distribution (Figure 3), where particle concentrations reduce most in relative terms across the size range from 20 - 200 nm in diameter (10 - 100 nm radius), encompassing the Aitken mode and much of the accumulation-mode peak. Crucially, the number of particles greater than 50 nm in diameter (N50) has reduced and this is likely to affect the availability of cloud condensation nuclei (CCN). The reduction of particle number concentrations appears to be driven by a reduction in the nucleation of new particles in the upper troposphere (Figure 4a). This is a region of the atmosphere where nucleation is typically most intense in the model so the reduction affects aerosol numbers globally. Indeed, there is a drop in zonal mean N50 across all latitudes and through the depth of the troposphere (Figure 4b). This follows through to a reduction in cloud droplet number concentration (CDNC) across all latitudes and heights in the multi-annual zonal means (Figure 4c) where liquid clouds are present in the model. The changes in N50 vary regionally as do the impacts on CDNC (Figure 5a, b). The strongest reductions in CDNC at 1 km occur over the oceans, especially in tropical and sub-tropical latitude zones where stratocumulus typically reside. These are statistically significant across most ocean regions and, as expected, lead to significant increases in cloud droplet effective radius (Reff) at 1 km, averaging around 0.1 - 0.2 m over much of the oceans (Fig. 5c). The results strongly indicate that the so-called Twomey effect (Twomey, 1977) is weakened in the piClim-CH4 simulation relative to *piClim-control*, resulting in less reflective clouds and the positive indirect ERF from aci of  $0.28 \pm 0.06/0.30 \pm 0.04$  W m⁻² (Tables 2, 3). Although defined differently, the estimated aci response here is consistent with the UKESM1 cloud adjustment of  $0.24 \text{ W} \text{ m}^{-2}$  from the radiative kernel difference method used in Thornhill et al. (2021b) – this is due to the corrections for cloud masking in Thornhill et al. (2021b) cancelling out or being equal to zero in the approaches (Elimination Method or Single Forcing Method) used here.

# 3.4.2 Aerosol-chemical feedback mechanisms

To understand why such changes in aerosol microphysics have occurred requires a more detailed investigation of changes in oxidation rates and the life cycle of aerosol-chemical processes. Table 5 shows a full gas-phase and aerosol budget for sulfur species and organic matter (OM) from the *piClim-control* and *piClim-CH4* simulations and Figure 6 shows a schematic of the main processes involved in the secondary formation of sulfate  $(SO_4)$  aerosol in UKESM1 (Sellar et al., 2019). Dimethyl sulphide (DMS) is oxidised in the gas phase to form sulfur dioxide (SO₂). In the PI atmosphere, DMS is oxidised by the hydroxyl (OH) radical  $(14.38 \pm 0.09 \text{ Tg (S) yr}^{-1})$ , nitrate  $(2.03 \pm 0.03 \text{ Tg (S) yr}^{-1})$  and oxygen atoms  $(0.18 \pm 0.01 \text{ Tg} (S) \text{ yr}^{-1})$ . Together with carbonyl sulphide (COS) photolysis and oxidation, they account for  $16.72 \pm 0.10$  Tg (S) yr⁻¹ of the PI global SO₂ source. The remaining  $SO_2$  source is primary, amounting to 14.82 Tg (S) yr⁻¹.  $SO_2$  is then oxidised by OH and  $O_3$  in the gas phase and by hydrogen peroxide ( $H_2O_2$ ) and  $O_3$  in the aqueous phase (Table 5), with the 3 principal pathways shown in Figure 7. Oxidation by OH accounts for 40.7 % of PI SO₂ oxidation to produce sulfuric acid  $(H_2SO_4)$ . New particle formation arises from the binary homogeneous nucleation of  $H_2SO_4$  and water in the free troposphere (Vehkamäki et al., 2002), leading to an increase in nucleation mode number concentration and  $SO_4$ aerosol mass (Figure 6) and accounting for 0.8 % of PI secondary SO₄ aerosol production. Gas-phase H₂SO₄ also condenses onto pre-existing aerosol, increasing  $SO_4$  mass without changing aerosol number concentration and contributes 46.7 % to the secondary SO₄ aerosol production. SO₂ is also oxidised via dissolution into cloud droplets followed by reaction with  $H_2O_2$  or  $O_3$ . Fluxes from these aqueous-phase reactions update the  $SO_4$  mass in both the accumulation and coarse mode aerosol with no change in aerosol number concentration, and account for 43.3 and 9.1 % of secondary SO₄ production, respectively. The resulting PI SO₄ burden is  $0.456 \pm 0.005$  Tg (S). Wet scavenging accounts for up to 85 % of SO₄ aerosol removal, leading to a lifetime of  $9.17 \pm 0.12$  days.

Table 5 indicates that in the PI atmosphere, primary emissions of OM from land and marine sources contribute  $49.25 \pm 0.01$  Tg (OM) yr⁻¹, with the latter coupled to the ocean biogeochemistry scheme (Sellar et al., 2019; Mulcahy et al., 2020). Secondary formation of OM is via oxidation of monoterpenes and the gas-phase product condenses onto pre-existing aerosol (Kelly et al., 2018; Mulcahy et al., 2020) i.e., increasing OM aerosol mass but with no change in aerosol number concentration. In the PI atmosphere, secondary formation of OM aerosol accounts for 43.7 % of the global OM source. Close to 80 % of OM is removed by wet scavenging, with the remainder by dry deposition, leading to a PI aerosol burden of  $1.28 \pm 0.02$  Tg (OM) and a lifetime of  $5.29 \pm 0.05$  days. A full description of the GLOMAP-mode aerosol scheme and its performance in UKESM1 for the recent past can be found in Mulcahy et al. (2020).

In *piClim-CH*₄, the PI-to-PD increase in CH₄ concentration does not change the total DMS source or DMS oxidation flux relative to the PI atmosphere (Table 5). However, CH₄-driven changes in oxidants change the relative contributions of the different DMS oxidation pathways. For example, oxidation by OH reduces by 4 % while oxidation by NO₃ increases by 22 %. These changes are most evident in the DMS burden over the Southern Ocean, where reductions in oxidation by OH change the regional distribution of secondary sources of SO₂ (not shown). On a global annual mean basis, the DMS burden and lifetime both increase (Table 5).

The PI-to-PD increase in  $CH_4$  also alters the relative contribution of the different  $SO_2$  oxidation pathways (Figure 7). Oxidation of  $SO_2$  by OH reduces from  $8.01 \pm 0.07$  Tg (S) yr⁻¹ to  $6.83 \pm 0.06$  Tg (S) yr⁻¹ - a decrease of 14.7 %. Oxidation by  $H_2O_2$  increases by 12.4 % and accounts for over 50 % of  $SO_2$ oxidation. There is little change in the aqueous-phase oxidation by  $O_3$  (+0.2 %) or in the total amount of  $SO_2$  being oxidised, as was the case for DMS. The change in oxidation by OH is consistent with the CH₄ lifetime increasing by 21 % in *piClim-CH4* relative to *piClim-control* (O'Connor et al., 2021). Given that the gas-phase oxidation of  $SO_2$  by OH is the only pathway that gives rise to new particle formation in UKESM1, a change in the relative contributions of the different  $SO_2$  oxidation pathways *alone* may lead to a change in aerosol size distribution and hence, cloud activation (Abdul-Razzak and Ghan, 2000). A similar mechanism, albeit due to sensitivity of the aqueous-phase oxidation of  $SO_2$  by  $O_3$  to changes in cloud water pH, was found to affect aerosol formation rates, cloud activation, and aerosol forcing by Turnock et al. (2019) although the pH is fixed in the configuration used here (Mulcahy et al., 2020).

Due to oxidant changes, the CH₄ increase in piClim-CH4 leads to less new particle formation; nucleation rates of H₂SO₄ decrease from 0.137 ± 0.003 to 0.126 ± 0.003 Tg (S) yr⁻¹, amounting to a decrease of 8.0 %. This helps to explain why the concentration of nucleation-mode particles has reduced (Figure 4a). Condensation of gas-phase H₂SO₄ also decreases, with the smallest and largest reductions evident in condensation rates onto the nucleation and coarse modes of 8.3 and 21.1 %, respectively. On the other hand, condensation rates onto accumulation and coarse mode aerosol following aqueous-phase oxidation of SO₂ via H₂O₂ increase from 7.20 ± 0.04 to 8.08 ± 0.06 Tg (S) yr⁻¹. The net effect of these changes is that there is less SO₄ mass in the nucleation (-1.8 %) and accumulation (-3.8 %) modes, with a very marginal increase in the Aitken mode (less than 1 %) and a near-zero change in the coarse mode. Together, these combine to give a SO₄ burden in *piClim-CH4* of 0.446 ± 0.005 Tg (S), which is only 2 % lower than in the PI atmosphere.

In the case of OM,  $CH_4$  changes the relative contributions of the different monoterpene oxidation pathways although the total secondary production of OM is unchanged. Oxidation by OH decreases by 4.8 %, while oxidation by NO₃ and O₃ increase by 2.1 and 2.4 %, respectively. As a result, the monoterpene burden reduces by 6 % in the global annual mean. Secondary OM production, via condensation onto pre-existing aerosol of the condensable vapour product from monoterpene oxidation, remains unchanged (Table 5). However, condensation onto the nucleation and Aitken soluble modes decreases by 4.6 and 1.5 %, respectively, while that onto the Aitken insoluble, accumulation and coarse modes increases marginally. This is suggestive that changes in gas-to-particle partitioning of OM onto pre-existing aerosol also have the potential to modulate the aerosol size distribution further. Although the total OM burden is unchanged, there is less OM mass in all modes, except for the Aitken insoluble mode. Less mass in the smaller modes also reduces the condensational growth of particles to sizes that can contribute to CCN, thereby directly leading to a shift in the aerosol size distribution (Figure 3) towards one with fewer particles large enough to act as CCN (Figure 4) and a weakening of the Twomey effect (Section 3.4.1).

#### 3.5 Thermodynamic feedbacks on cloud

The analyses presented in Table 2 and 3 show that the cloud radiative effect (CRE) played a significant role in the CH₄ ERF. In total, the CRE accounts for 0.12 W m⁻² of the total CH₄ ERF (with all interactions included) but the individual SW and LW components are much larger (0.50 W m⁻² for SW and -0.38 W m⁻² for LW). Whilst the aci were a strong contributor to the SW CRE (amounting to 0.28 - 0.30 W m⁻²) and wholly responsible for the cloud adjustment as defined in Thornhill et al. (2021b), some 0.23 W m⁻² of the SW CRE occurs with aci disabled. The negative LW CRE component is driven almost exclusively by the non-aerosol interactions; the perturbations in CH₄, WV and O₃ together build towards the negative LW CRE of -0.35 W m⁻² in the absence of the aci. It is therefore clear that much of the change in the CRE are related to thermodynamic feedbacks, such as changes in temperature and atmospheric circulation, rather than microphysical interactions.

To investigate such thermodynamic feedbacks, we analyse the pair of simulations with PI or PD  $CH_4$  where interactive aci were eliminated (as listed in the second row of Table 2). There are increases in temperature in the troposphere (Figure 8a), especially in the upper troposphere and the warming peaks at around 0.5 K across the tropical tropopause. Some cooling occurs at higher levels in the stratosphere. Along with the warming patterns are statistically significant reductions in cloud fractions (Figure 8b). For instance, in the deep tropics, cloud cover has reduced at mid and upper levels of the troposphere, which is indicative of suppressed convection associated with the warming and stabilization of the troposphere. There are also statistically significant reductions in cloud cover in the mid-latitudes around 45  $^{\circ}S$  and 40  $^{\circ}N$  that extend through the range of the troposphere. At high latitudes, there appears to be strong changes in cloud of both positive and negative sign, but these are not statistically significant. Overall, the global-mean cloud fraction reduces by 0.25~%and there were decreases of 1.0 and 0.9~% in global-mean liquid water path and ice water path, respectively. The decreased cloud explains the negative LW CRE (increased outgoing LW), and positive SW CRE (less reflection). In addition, global-mean precipitation decreases by 0.013 mm/day (0.4 %), indicating that there was a slight slowing down of the hydrological cycle. This is consistent with the suppression of convection, which is expected for forcing agents that increase absorption of radiation in the troposphere. The  $CH_4$  contributes SW and LW absorption (Figure 2) and increased tropospheric  $O_3$  contributes to the absorption of SW in the troposphere. These decreases in precipitation, cloud and CRE can be regarded as so-called "rapid responses" (e.g. Smith et al., 2018), since the sea surface temperatures in these simulations were fixed. Slow feedbacks from longer-term climate warming could be different or even have the opposite tendency to the fast feedbacks.

# 3.6 Emission-Based Estimates of Forcing

The direct and indirect  $CH_4$  ERFs quantified here are based on the observed change in global mean concentration between 1850 and 2014 (Meinhausen et al., 2017) and are referred to as concentration-based or abundance-based ERFs. The abundance-based approach used here is similar to that taken for previous estimates of the direct and total  $CH_4$  forcing (Andrews, 2014; Etminan et al., 2016; Smith et al., 2018; O'Connor et al., 2021; Thornhill et al., 2021b). However, the chemical coupling between  $CH_4$  and its own sink, via OH, means that an increase in  $\mathrm{CH}_4$  emissions decreases OH, increases the  $\mathrm{CH}_4$  lifetime, and increases the resulting atmospheric concentration (Prather et al., 2001). The CH₄ lifetime and atmospheric abundance also depend on emissions of other tropospheric O₃ precursors, with the PI-to-PD increase in volatile organic compound (VOC) and carbon monoxide (CO) emissions contributing to an increase in  $CH_4$  lifetime whereas the increase in nitrogen oxides (NOx) emissions causes a decrease (Stevenson et al., 2020). Together, it means that the observed  $CH_4$ concentration change is lower than would arise from the PI-to-PD change in  $CH_4$ emissions alone. As a result, an emissions-based forcing estimate, based solely on the PI-to-PD increase in  $\mathrm{CH}_4$  emissions, could be larger than an abundancebased estimate by as much as 25 % (Shindell et al., 2005).

Outside of CMIP6, ESMs including UKESM1 are starting to include more interactive  $CH_4$  cycles, with  $CH_4$  emissions-driven rather than concentration-driven (Ocko et al., 2018; Kleinen et al., 2020; Folberth et al., 2021). Forcing estimates from an emissions-based perspective, in the case of  $CH_4$ , provide a more direct attribution of the forcing to changing emissions and have greater relevance for policy makers (Shindell et al., 2013). Therefore, understanding and quantifying the potential differences in forcing between the current generation of CMIP6 models with  $CH_4$  concentration-driven and those models driven by  $CH_4$  emissions is important. Here, we attempt to convert the UKESM1 direct and indirect abundance-based  $CH_4$  ERFs to emissions-based estimates.

To do this for the direct  $CH_4$  radiative forcing and ERF, we make use of additional experiments from the AerChemMIP protocol (Collins et al., 2017): *piClim-NOx* and *piClim-VOC*, in which PI-to-PD perturbations to the anthropogenic emissions of (i) NOx and (ii) VOCs and CO were applied, respectively. The model-diagnosed change in total  $CH_4$  lifetime in relation to *piClim-control* is used to calculate the equilibrium  $CH_4$  concentrations from the *piClim-CH4*, *piClim-NOx* and *piClim-VOC* experiments following O'Connor et al. (2021). From the difference between the prescribed and equilibrium  $CH_4$  concentrations and the UKESM1 direct  $CH_4$  ERF, a PD emissions-based direct radiative forcing by  $CH_4$  is estimated to be 0.67 W m⁻². This comprises the direct  $CH_4$  concentration-based radiative forcing of 0.56 W m⁻² and additional individual contributions from  $CH_4$ , NOx, and VOCs/CO (via their influence on  $CH_4$  lifetime) of 0.22, -0.19, and 0.08 W m⁻², respectively (Table 6). The estimate of 0.56 W m⁻² from Etminan et al. (2016), and is consistent with the findings of Shindell et al. (2005). Using the direct  $CH_4$  ERF from UKESM1 of 0.54 W m⁻² (Table 2) and applying the same scaling, the direct emissions-based  $CH_4$  ERF from UKESM1 is 0.65 ± 0.05 W m⁻².

In relation to the indirect  $\mathrm{O}_3$  forcing from  $\mathrm{CH}_4,$  the study by O'Connor et al. (2021) found that the tropospheric O₃ stratospherically-adjusted radiative forcing (SARF) for the year 2014 due to changes in  $CH_4$  since the PI period from concentration-based and emissions-based perspectives is 0.14 and 0.21 W m⁻², respectively. The emissions-based estimate is comparable to that from Shindell et al. (2005) for the year 1998  $(0.20 \text{ W m}^{-2})$  relative to 1750 despite the  $CH_4$  concentration change in that study being larger than that applied here (1209 cf. 1023 ppb). However, they noted from their simulations that the  $O_3$ response to a positive  $CH_4$  perturbation at the PI is larger than a negative perturbation applied at the PD by 20 %. Therefore, scaling our emissions-based estimate by the ratio of the concentration changes between the two studies gives a revised UKESM1 estimate of 0.25 W m⁻² for the 1750-1998 period, which is indeed approximately 20 % larger than the estimate from their PD simulations. Taking the UKESM1 indirect abundance-based ERFs from O₃ of  $0.13 \pm 0.05$  and  $0.20 \pm 0.04$  W m⁻² from the Elimination (Table 2) and Single-Forcing (Table 3) methods, respectively, emission-based ERFs are likely to be  $0.19 \pm 0.07$  and  $0.30 \pm 0.06$  W m⁻², respectively. These ERF values are reasonably consistent with the SARF of  $0.21 \text{ W m}^{-2}$  from O'Connor et al. (2021) and reflect that rapid adjustments in the O₃ ERF are small in magnitude and nearly sum to zero (Skeie et al., 2020).

In the case of stratospheric WV, adopting the approach of scaling the direct emissions-based  $CH_4$  ERF of 0.65 W m⁻² by 15 % yields an indirect emissionsbased ERF from WV of  $0.10 \pm 0.01$  W m⁻². However, this seems rather high relative to the abundance-based ERF from the Single-Forcing Method of  $0.02 \pm 0.04$  W m⁻² (Section 3.3). Therefore, as an alternative, we apply the ratio of the direct emissions-based to the abundance-based  $CH_4$  ERFs to the indirect abundance-based WV ERF, leading to an estimate of  $0.02 \pm 0.05$  W m⁻². Finally, although aci are non-linear, a similar approach leads to a potential emissions-based indirect ERF from aci of 0.35  $\pm$  0.07 and 0.36  $\pm$  0.05 W m⁻² from the Elimination and the Single-Forcing methods, respectively. Taking the emission-based ERFs from the Single-Forcing method alone, we calculate a total PD (Year 2014) emissions-based  $\rm CH_4$  ERF of 1.33  $\pm$  0.11 W m^{-2} relative to the PI (Year 1850) period. This is higher than the total abundance-based ERF by 37 % and highlights the importance of historical changes in  $CH_4$  emissions in the PD forcing of climate. It also emphasises the potential role of  $CH_4$  in mitigating the near-term rate of climate change (Allen et al., 2018; Abernethy et al., 2021).

# 4 Conclusions

The PI-to-PD change in methane (CH₄) concentration from 808 to 1831 ppb leads to a global mean ERF of  $0.97 \pm 0.04$  W m⁻² (O'Connor et al., 2021), with the majority of the forcing in the clear-sky (CS) longwave (LW) com-

ponent. Of this forcing, the direct concentration-based CH₄ contribution is  $0.54 \pm 0.04$  W m⁻² and is consistent with line by line radiative transfer calculations (Etiminan et al., 2016) and is better represented in UKESM1 than in its predecessor model, HadGEM2. An indirect O₃ ERF of  $0.13 \pm 0.05$  W m⁻² from the Elimination Method and  $0.20 \pm 0.04$  W m⁻² from the Single-Forcing Method is attributable to the CH₄ concentration increase, which is largely due to the tropospheric O₃ increase despite significant O₃ decreases in the stratosphere. The production of water vapor due to changes in CH₄ leads to a weakly positive ERF of  $0.07 \pm 0.05/0.02 \pm 0.04$  W m⁻² – these values are consistent with previous estimates based on the stratospherically-adjusted radiative forcing metric (Hansen et al., 2005; Myhre et al., 2013), suggesting that the choice of forcing metric does not have a major impact on our understanding of the role of CH₄-driven changes in WV in climate forcing.

The PI-to-PD CH₄ increase in concentration also gives rise to a positive aerosol ERF of 0.28-0.30 W m⁻² through aerosol-cloud interactions. CH₄-driven changes in oxidants, particularly OH, alter the relative contributions of the different sulfur dioxide (SO₂) oxidation pathways, leading to a reduction in new particle formation, a decrease in the number concentration of cloud condensation nuclei and cloud droplets, with a corresponding increase in cloud droplet effective radius. However, the forcing from aerosol-radiation interactions is negligible, consistent with the global mean aerosol optical depth changing by less than 2 %. This study also confirms that the strong positive cloud adjustment in UKESM1, as defined and quantified in Thornhill et al. (2021b), is aerosol-mediated.

Previous studies have found an aerosol forcing attributable to  $CH_4$  and/or oxidant changes. Shindell et al. (2009), for example, found a large reduction in the sulfate burden on a global scale (-11 %), resulting in an increase of  $\sim 10$  %  $(\sim 20-40 \%)$  in the PD 100-year global warming potential of CH₄ when chemistryaerosol interactions and ari (ari and aci) were considered. Kurtén et al. (2011) reported a global mean decrease in CDNC of 18 %, reduced cloudiness, and a strong positive aerosol forcing  $(2.32 \text{ W m}^{-2})$  in a scenario in which they applied a 10-fold increase in  $CH_4$ , the bulk of which was due to aerosol indirect effects  $(2.06 \text{ W m}^{-2})$ . More recently, Karset et al. (2018) found that the magnitude of the PD aerosol forcing reduced by 19 % (-1.32 to -1.07 W m⁻²) when the PI control simulation included PI oxidants rather than PD oxidants. The different oxidants cause greater condensate production relative to the amount of aerosol formed via nucleation, resulting in a shift in the aerosol size distribution towards larger particles, leading to cloud brightening in the PI atmosphere. The findings here are qualitatively consistent with these previous studies. However, there is disagreement on the extent to which the aerosol forcing is due to ari and/or aci, which warrants further investigation.

The inclusion of chemistry-aerosol interactions with aerosol-cloud interactions leads to a positive CRE in the PD  $CH_4$  ERF from UKESM1. Although other models have a positive cloud adjustment associated with  $CH_4$  in the AerChem-MIP models (Thornhill et al., 2021b), it was not clear why the cloud adjust-

ments varied in both sign and magnitude. This study, however, provides a process-based understanding of what is driving the positive CRE in UKESM1 and confirms that it is a combination of microphysical aerosol-cloud interactions and thermodynamics adjustments. The microphysical impacts occur due to CH₄-driven changes in oxidants in UKESM1 that alter cloud activation and reflectivity, leading to a contribution to the CRE of 0.28-0.30 W m⁻². Although defined differently, this is consistent with the positive UKESM1 cloud adjustment from Thornhill et al. (2021b). The thermodynamic effects are related to the radiative heating and stabilization of the upper troposphere, which on the whole reduced cloud cover and convection. This led to a negative CRE of -0.12 W m⁻² due to a dominant negative LW CRE of -0.35 W m⁻² and a positive SW CRE of 0.23 W m⁻². Overall, this means a CH₄-driven net CRE of 0.12 W m⁻². The cloud effects and other non-cloud forcing components added in a reasonably linear manner in our series of experiments, confirming that the assumption of linearity in radiative kernel analysis is valid.

If the contribution of aci to the CRE was robust across models, the results would have wider implications for the role of  $CH_4$  in historical and future climate and/or future climate mitigation. For example, future climate forcing and the Earth System response to continuing increases in anthropogenic emissions of  $CH_4$  (e.g., Saunois et al., 2020; Jackson et al., 2020) and/or from feedbacks on natural  $CH_4$  emissions (e.g., O'Connor et al., 2010; Dean et al., 2018; Gedney et al., 2019) would be greater than realised to date.  $CH_4$  mitigation and  $CH_4$ removal may be even more effective in reducing the total anthropogenic forcing on the Earth's radiative balance and the near-term climate response (e.g., Allen et al., 2021; Abernethy et al., 2021). However, the multi-model assessment of Thornhill et al. (2021b) suggests that the cloud adjustment in UKESM1 is anomalously large with respect to the other AerChemMIP models. A number of factors could be driving this: (1) an anomalous  $CH_4$ -driven oxidant response in UKESM1, (2) the lack of alternative nucleation mechanisms in UKESM1, such as boundary layer nucleation, and/or (3) the cloud response to aerosols in UKESM1 being too strong.

In relation to the oxidant response, the  $CH_4$ -OH feedback factor (Fiore et al., 2009) from UKESM1 appears to be consistent with other models (Thornhill et al., 2021b), suggesting that the OH response, at least, is reasonable. In relation to nucleation, Gordan et al. (2016) demonstrated how the inclusion of organic-mediated boundary layer nucleation could weaken the aerosol forcing by nearly 30 % by increasing the CDNC in the PI atmosphere to a greater extent than in the PD period. While boundary layer nucleation is not included in the UKESM1 simulations here, it has been found to improve model biases in PD aerosol number concentrations (Ranjithkumar et al. 2021). For the cloud response to aerosols, Malavelle et al. (2017) showed that aci seem to be more realistic in the HadGEM3 model (i.e., in the physical model underpinning UKESM1) than in other models by evaluating the response to a large volcanic perturbation using observations of cloud properties. However, McCoy et al. (2020) show that the PD-PI change in CDNC is inconsistent with observational

proxies as well as being outside of the range of AeroCom models. This could be due to CDNC being too high in the northern hemisphere in response to anthropogenic aerosol emissions or insufficient representation of background natural aerosol, including a lack of representation of boundary layer nucleation.

Nevertheless, these results indicate the importance of including interactive chemistry (and chemistry-aerosol-cloud interactions) in ESMs when quantifying PD climate forcing. Such interactions are relevant to forcings from gas-phase constituents (O'Connor et al., 2021) as well as from the aerosol phase (Karset et al., 2018). The study also suggests that rapid adjustments included in the ERF framework should include chemical as well as physical adjustments to fully account for ES interactions. This is consistent with a recent assessment by Ramaswamy et al. (2019) who concluded that the radiative forcing concept is simple but needs to increasingly account for complex ES processes.

### Acknowledgments

The development of the UK's Earth System Model, UKESM1, was funded by the Met Office Hadley Centre Climate Programme funded by BEIS and Defra (GA01101) and by the National Environmental Research Council (NERC) national capability grant for the UK Earth System Modelling project, grant number NE/N017951/1. FMO'C, TA, BTJ, and JPM were funded by the Met Office Hadley Centre Climate Programme funded by BEIS and Defra (GA01101). FMO'C also acknowledges the EU Horizon 2020 Research Programme CRESCENDO (grant agreement number 641816) and ESM2025 (grant agreement number 101003536) projects.

Table 2. Effective radiative forcing (ERF) and its clear-sky (CS) and cloud radiative effect (CRE) components in the longwave (LW) and shortwave (SW) based on Eqn. (6) and including an estimate of the standard error, calculated at the present day (PD; Year 2014) relative to the pre-industrial period (PI;

Year 1850) from a PI-to-PD methane (CH₄) perturbation in concentration using the "Elimination Method" pairs in Table 1. ERFs for individual forcing agents and/or interactions are inferred by differencing the ERF between two successive "Elimination Method" pairs.

Table 5: Aerosol and gas-phase budget terms for dimethyl sulphide (DMS), sulfur dioxide (SO₂), sulfate (SO₄) aerosol, and organic matter (OM) in UKESM1, based on the latter 30 years of the *piClim-control* and *piClim-CH*4 simulations. Units of production and loss are in Tg (S) yr⁻¹ for the sulfur species and in units of Tg (OM) yr⁻¹ for OM, where the ratio of carbon to OM is 1.0:1.4. Units of burden are in Tg (S) or Tg (OM) and the lifetime is in days. Of the aqueousphase SO₂ oxidation fluxes, 25 % of the SO₂ is assumed to re-evaporate from the aqueous phase into the atmosphere and does not form SO₄ aerosol.

Table 6. Table indicating prescribed global mean  $CH_4$  concentrations, total  $CH_4$  lifetime, equilibrium  $CH_4$  concentrations and the additional RF contributions from the *piClim-NOx*, *piClim-VOC*, and *piClim-CH4* simulations to the emissions-based estimate of the direct  $CH_4$  RF at the PD (Year 2014) relative to PI (Year 1850).

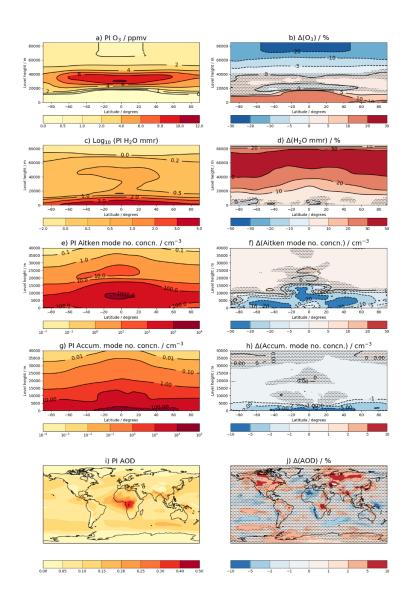

Figure 1. Multi-annual zonal mean distributions of a)  $O_3$ , c) WV, e) Aitken mode aerosol number concentration, g) Accumulation mode aerosol number concentration, and multi-annual global distribution of i) aerosol optical depth (AOD) in the pre-industrial (PI; Year 1850) period. The relative changes in

 $O_3$ , WV and AOD due to the increase in  $CH_4$  concentration between the PI and the present day (PD; Year 2014) are shown in b), d), and j), respectively, while the absolute changes in Aitken and Accumulation mode aerosol number concentrations are shown in f) and h), respectively. Stippled areas show where the differences are not statistically significant at the 95 % confidence interval.

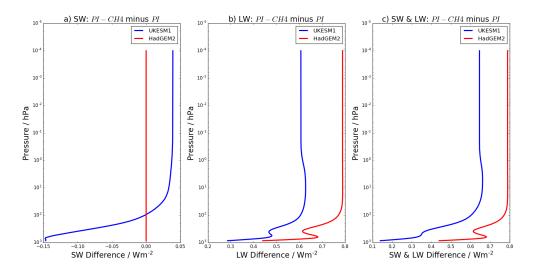

Figure 2. Comparison between two test cases (*PI* and *PI-CH4*) using the standalone SOCRATES radiation scheme with spectral data from HadGEM2 and UKESM1. Differences in the net outgoing radiative fluxes are shown for the shortwave (SW) in a), longwave (LW) in b), and SW&LW combined in c), using the sign convention that incoming radiative fluxes are positive and outgoing fluxes are negative.

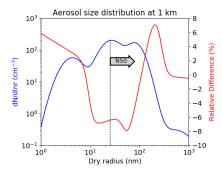

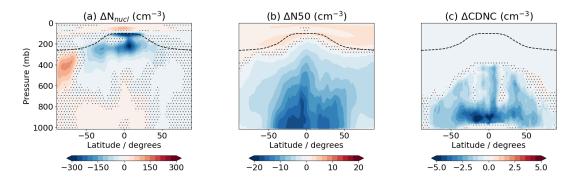

Figure 3: Global annual mean aerosol size distribution at 1 km in altitude in the PI atmosphere (blue; left axis) and the relative difference in the size distribution due to the PI-to-PD perturbation in  $CH_4$  (red; right axis), based on the latter 30 years of the 45-year long simulations. A vertical line marks those particles

that are large enough to contribute to N50 in the PI atmosphere.

Figure 4. Multi-annual zonal mean changes in aerosol number concentrations, driven by the PI-to-PD change in  $CH_4$  concentration in the *piClim-CH4* simulation. Results include changes to (a) nucleation-mode particles, (b) number of particles greater than 50 nm in diameter, and (c) number of particles activated into cloud condensation nuclei. Stippled areas show where the differences are not statistically significant at the 95 % confidence interval.

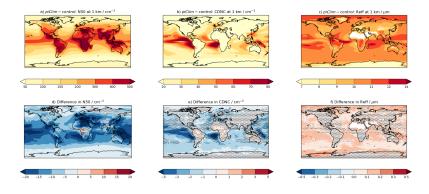

Figure 5. Global distributions of multi-annual mean a) N50, b) cloud droplet number concentration (CDNC) and c) cloud droplet effective radius (Reff) at 1km height and differences as a result of the PI-to-PD perturbation in  $CH_4$  in d), e), and f). Units are in cm⁻³ for N50 and CDNC and in m for Reff.

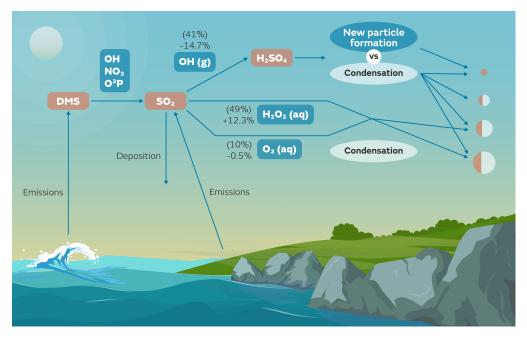

Figure 6: Schematic showing the mechanism for aerosol forcing attributable to methane at the present-day (PD; Year 2014) relative to the pre-industrial (PI; Year 1850). The relative contributions of the different oxidation pathways of sulfur dioxide (SO₂) lead to a change in the aerosol size distribution. Sulfur species include dimethyl sulfide (DMS) and sulfuric acid (H₂SO₄). Oxidants include hydroxyl (OH), nitrate (NO₃), atomic oxygen (O³P), hydrogen peroxide (H₂O₂) and ozone (O₃). The numbers in parentheses indicate the percentage of the total SO₂ oxidation that is oxidised through a particular pathway and the percentage below is the relative change in SO₂ oxidation as a result of the increase in methane (CH₄) concentration from PI to PD levels.

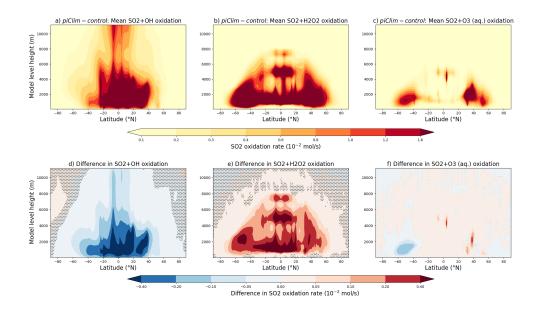

Figure 7: Multi-annual zonal mean distributions of sulfur dioxide  $(SO_2)$  oxidation fluxes via a) hydroxyl (OH), b) hydrogen peroxide  $(H_2O_2)$ , and c) ozone  $(O_3)$  in *piClim-control*. The difference in the oxidation rates as a result of the PI-to-PD methane increase is shown in d), e), and f). Units are in  $10^{-2}$  moles (S) per second.

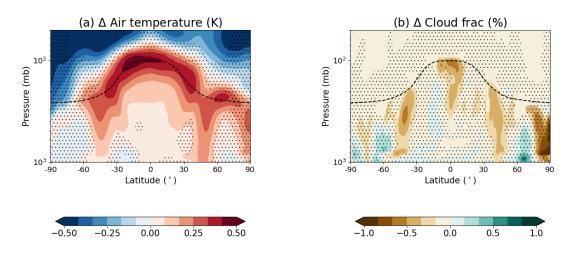

Figure 8. Multi-annual mean zonal mean changes in (a) temperature, (b) cloud fraction from the large-scale stratiform cloud scheme based on the difference between *piClim-CH4* and *piClim-control*, where aerosol-cloud interactions were suppressed.
