## Abstract

Little is known about the sources and age of C respired from tree roots. Previous research in tree stems has identified two functional pools of non-structural carbohydrates (NSC): an ‘active’ pool supplied directly from canopy photo-assimilates that supports metabolism and a ‘stored’ pool used when fresh C supplies are limited. We compared the C isotope composition of water soluble NSC and respired CO<sub>2</sub> for aspen roots (*Populus tremula* hybrids) that were cut off fresh C supply via stem-girdling and prolonged incubation of excised roots. We used bomb radiocarbon to estimate the time elapsed since C fixation for respired CO<sub>2</sub>, water-soluble C, and structural  $\alpha$ -cellulose. While freshly excised roots respired CO<sub>2</sub> with mean age <1 yr, within a week the age increased to 1.6-2.9 yr. Freshly excised roots from trees girdled ~3 months previously had similar respiration rates and NSC stocks as un-girdled trees, but respired older C (~1.2 yr). We estimate the NSC in girdled roots must be replaced 5-7 times by reserves remobilized from root-external sources. Using a mixing model and observed correlations between  $\Delta^{14}\text{C}$  of water-soluble C and  $\alpha$ -cellulose, we estimate ~30% of C is ‘active’ (~5 mg C g<sup>-1</sup>).
