Abstract

Purpose Using three-dimensional speckle tracking echocardiography (3D-STE) to evaluate left ventricular (LV) function in patients with triple vessel coronary artery disease(TVD) without myocardial infarction. **Methods** Sixty patients with TVD without myocardial infarction were divided into two groups according to the results of coronary angiography. Group B (n=31):50%[?]the stenosis rates of all triple vessel coronary artery;75%; Group C (n=29):the stenosis rates of all triple vessel coronary artery[?]75%. Thirty healthy subjects were recruited as the group A. We measured LV end-diastolic and end-systolic volume (LVEDV, LVESV) and LV ejection fraction (LVEF) using real-time three-dimensional echocardiography. The 3D-STE parameters of LV included global longitudinal strain (GLS), global area strain (GAS), global radial strain (GRS) and global circumferential strain (GCS). **Results** In group C, LVEDV and LVESV were significantly increased (all $P<0.05$), while LVEF, GLS, GRS, GCS and GAS were significantly decreased compared with groups A and B (all $P<0.05$). In groups A and B, there were no statistical differences in LVEDV, LVESV and LVEF. However, GLS, GCS and GAS were lower in group B than in group A (all $P<0.05$). **Conclusion** Our study shows that 3D-STE can evaluate the LV function in patients with triple vessel coronary artery disease without myocardial infarction through multiple strain parameters.

Introduction

Coronary heart disease (CHD) has been a hot spot in cardiovascular disease research. It is a heart disease caused by the formation of coronary atherosclerotic plaque, which result in stenosis or obstruction of the vascular lumen, leading to myocardial ischemia, hypoxia and necrosis. According to the report published in 2016, CHD accounts for 20% of deaths in Europe, and is still one of the diseases with the highest morbidity and mortality in the world^[1,2]. CHD involving three vessels disease (TVD) is a more extensive and serious disease than common CHD, and the change of left ventricular (LV) function was earlier than that of structure. The main function of the LV is to transport blood to all parts of the body and undertake the blood supply to the whole body. So the effective evaluation of LV function in patients with TVD is very meaningful to the treatment and prognosis of patients. Traditional echocardiography has become the first choice for clinicians to diagnose heart disease, but it is less sensitive in early identification of cardiac function changes^[3]. The three-dimensional speckle tracking echocardiography (3D-STE) is a quantitative tool to evaluate LV function with high accuracy and reliability^[4]. Nesser et al.^[5] found that 3D-STE in assessment of LV systolic function had a remarkable correlation with cardiac MRI. 3D-STE can provide more cardiac function evaluation indexes for clinical and detect LV subclinical myocardial injury early^[6-8]. This study used 3D-STE to quantitatively analyze the changes of systolic LV strain parameters and evaluate LV function in patients with TVD without myocardial infarction.

Methods

Study population and grouping principles

Our study enrolled patients, who had been clinically diagnosed with CHD at the department of cardiology, from hospital admissions made between June 2019 and December 2020 in our hospital. Our diagnostic criteria for CHD was consistent with the diagnostic and therapeutic guidelines of CHD from the European Society of Cardiology (ESC) published in 2013^[9]. Among them, sixty patients with TVD were selected as the experimental group. Diagnostic criteria of TVD was as follows: coronary angiography showed that the diameter stenosis rates of three subepicardial vessels (left anterior descending coronary artery, circumflex coronary artery, right coronary artery) and / or their main branches were all $\geq 50\%$. 60 patients with TVD were divided into two groups: 31 patients with the stenosis rate of all triple vessel coronary artery $\geq 75\%$ served as group B (age, 45~77 years; mean age, 57.41 ± 8.29 years; ratio of females to males: 20:11), 29 patients with all three-vessel stenosis rate $\geq 75\%$ served as group C (age, 44~71 years; mean age, 57.37 ± 8.16 years; ratio of females to males: 20:9). At the same time, we recruited 30 gender and age-matched healthy subjects (age, 41~69 years; mean age, 55.43 ± 7.54 years; ratio of females to males: 18:12) as group A. And all of the above participants were in sinus rhythm.

Exclusion criteria included: 1) therapeutic history of coronary revascularization; 2) myocardial infarction; 3) cardiac injury caused by coronary heart disease-related complications, such as papillary muscle rupture, ventricular wall rupture, interventricular septal perforation; 4) cardiac enlargement and cardiac dysfunction resulted by other types of heart disease, such as dilated cardiomyopathy, congenital heart disease, rheumatic heart disease, chronic pulmonary heart disease, valvular disease; 5) combined with hypertension, diabetes, nephrotic syndrome that contribute to heart damage. We also excluded the poor quality images.

Before the examination, we recorded the basic information of all participants on the checklist including name, gender, age, height and weight, then calculated body mass index (BMI, kg/m²) and body surface area (BSA, m²). After taking a 10 min break, a physician who was blind the purpose of the study measured the blood pressure (BP) and the heart rate (HR) of all participants. And 4 mL venous blood samples were retrieved in fasting in the morning from three groups of participants, and the serum was obtained by centrifuging venous blood at 3000 r/min for 10 min and stored in the refrigerator (-30). Then the content of N-terminal pro-brain natriuretic peptide (NT-proBNP) of the serum were measure by photochemical method. LV end-diastolic pressure (LVEDP) was measured by left cardiac catheterization after coronary angiography in groups B and C, and the acquisition of ultrasonic images should be carried out within two days after left cardiac catheterization.

Conventional echocardiographic measurements

In our study, a GE Vivid E9 doppler ultrasound instrument equipped with an M5S-D probe (1.5-4.5MHz) was introduced to obtain 2-dimensional images. The ultrasound examination was conducted when the subjects lay in the left lateral decubitus position and keep steady breathing with connecting a three-lead electrocardiography (ECG). Three groups of participants completed an assessment of echocardiography from multiple views including the LV long-axis, apical 4-chamber and apical 2-chamber. We measured the conventional parameters which included interventricular septal thickness and LV posterior wall thickness at end-diastolic (IVSTd and PWTd), LV end-diastolic diameter (LVDd) and LV end-systolic diameter (LVDs), transmitral peak early and late inflow diastolic velocity (E and A), early-diastolic tissue velocity of septal and lateral mitral annulus (Sept e' and Lat e'), then computed respectively E/A and E'/mean e'.

Real-time three-dimensional echocardiography and 3D-STE measurements

To acquire 3D echocardiographic LV full volume images, we used a matrix-array 4V-D probe (1.7-3.3 MHz). In real-time dynamic three-dimensional pattern, the frame rates of echocardiographic image were 25-50 frames/s. When the entire LV myocardium, endocardium, and epicardium were clearly displayed in apical 4-chamber view, we told the patients to hold their breath after a calm breath in order to eliminate breathing motion artifacts. Furthermore, to make sure a clear image, it is necessary to adjust the buttons that control

the depth and width of the probe during the operation. Then turning into 4D full volume pattern, we continued to collect real-time dynamic three-dimensional images of LV in four consecutive cardiac cycles which can be analyzed with 3D-STE. At last, starting 4-dimensional automatic LV quantitative analysis software (4D-Auto LVQ) to analyze all the collected full-volume images. This software will automatically delineate the edocardial boundary of the LV, which can be manually adjusted if required. The parameters including LV end-diastolic volume (LVEDV), LV end-systolic volume (LVESV), LV ejection fraction (LVEF) were measured and strain curves for 17 segments of the LV wall were obtained. Global longitudinal strain (GLS), global area strain (GAS), global radial strain (GRS) and global circumferential strain (GCS) of 17 myocardial segments in each direction were got by computing the weighted average of the peak systolic strain values. The left atrial intima was traced in the same way to measure the left atrial maximum volume, and calculated the left atrial maximum volume index (LAVImax, LAVImax=LAVmax/BAS). Each parameter was measured three times by a physician, and the average value was taken.

Statistical analysis

We analyzed all data using SPSS 19.0 software (SPSS 19.0, Inc., Chicago, IL, USA). All continuous variables conforming to normal distribution were showed as mean values $\pm$ standard deviations. Comparisons of the gender among the three groups were made by using χ^2 -test. Differences of three groups were compared by analysis of one-way ANOVA. LSD-t test was used to compare the differences between two groups. For analyzing the correlations of NT-proBNP and LVEDP with 3D-STE parameters and in three groups, we used Pearson linear correlation analysis. The values of $P < 0.05$ demonstrated that the results were statistically significance.

Results

Clinical characteristics and NT-proBNP

There was no obvious difference among the three groups of participants in the age, gender, BMI, BP and HR (all $P > 0.05$). In terms of level of NT-proBNP, group C was the highest among three groups, and group B had higher NT-proBNP level than that in group A (all $P > 0.05$). LVEDP was increased in groups B and C, and LVEDP was increased in group C compared with group B ($P < 0.05$). (Shown in Table 1)

Conventional echocardiographic parameters

No difference was showed in IVSTd and PWTd among three groups (both $P > 0.05$). In group C, E/mean e', LVDs and LVDd were increased (all $P > 0.05$), while E/A, LVEF, Sept e' and Lat e' were decreased (all $P > 0.05$) compared to groups A and B. In group B, we found that E/mean e' was increased, while Sept e' and Lat e' were decreased compared with group A (all $P > 0.05$). There were no obvious difference in terms of LVDs, LVDd, E/A and LVEF between groups A and B (all $P > 0.05$). (Shown in Table 2)

3D and 3D-STE parameters

Compared with groups B and A, LVEDV and LVESV were obviously increased (all $P > 0.05$), whereas LVEF was obviously declined in group C ($P > 0.05$). The parameters of LVEDV, LVESV and LVEF were no obvious differences in groups A and B (all $P > 0.05$). The patients in group C had higher LAVImax compared to groups A and B, and LAVImax level for group B was higher than for group A. GLS, GRS, GCS, GAS in group C were obviously lower (all $P > 0.05$) than those in groups A and B. GLS, GCS and GAS in group B were lower than those in group A (all $P > 0.05$) and GRS was also reduced, but there was no difference ($P > 0.05$). (Shown in Table 3 and Figure 1)

Correlation analysis

In order to make the results more intuitive, we used the absolute values instead of negative value of three-dimensional strain parameters in the Pearson linear correlation. GLS, GRS, GCS and GAS were negatively related to NT-proBNP in group C ($r = -0.866$, $r = -0.587$, $r = -0.428$, $r = -0.600$, $P < 0.001$, $P = 0.001$, $P = 0.020$, $P = 0.010$). And GLS is the only parameter that demonstrated a negative relationship with NT-proBNP in group B ($r = -0.642$, $P < 0.010$). And correlation analysis showed that the absolute values of

three-dimensional strains were negatively correlated with LVEDP in groups B and C: GLS ($r_B=-0.664$, $P < 0.001$; $r_C=-0.832$, $P < 0.001$), GRS ($r_B=-0.449$, $P=0.011$; $r_C=-0.668$, $P < 0.001$), GCS ($r_B=-0.390$, $P = 0.030$; $r_C=-0.484$, $P=0.008$) and GAS($r_B = -0.468$, $P=0.008$; $r_C=-0.586$, $P = 0.001$).

Discussion

As a subtype of CHD, TVD is more serious than single-vessel and double-vessel disease, which has a higher incidence of cardiovascular events and mortality^[10]. At present, we need a technique to evaluate the changes of LV function early and accurately. Conventional echocardiography considers the LVEF is the most common parameter to evaluate myocardial systolic function^[11], but relevant studies have shown that the sensitivity of it is poor in detecting mild myocardial dysfunction^[12]. Speckle tracking is a new echocardiographic technique developed in recent years. At present, 2D-STE has been widely used in clinical and experimental research^[13,14]. But the limitation of 2D-STE is that the tracking of myocardial acoustic spots is limited to the two-dimensional section, which makes it untraceable when some of the spots move completely outside the two-dimensional section. The 3D-STE overcomes the 'out-of-plane' phenomenon of 2D-STE in scanning^[15,16]. It can quantitatively evaluate the deformation of regional myocardium in multiple directions, and reflect motion and function of myocardium in three-dimensional space more realistically and accurately^[17,18]. Crosby et al.^[19] study on local myocardial function using speckle tracking technology shows that 3D-STE can accurately identify the myocardium with local dysfunction.

In our study, the LV structure of the group B was no obvious difference, and LVEF was also within the normal range compared with group A. However, the group C had larger LV volume and lower LVEF than those in other two groups. The LV structure and LVEF can remain normal in group B, because the motion of myocardium in the ischemic region may be compensated by adjacent normal myocardium. With the aggravation of the degree of stenosis, the range of affected myocardium expands, and the LV function is gradually decompensated, resulting in cardiac enlargement and heart failure.

The myocardium of the LV is divided into three layers: the inner layer of the right hand spiral, the middle layer of the ring spiral and the outer layer of the left hand spiral^[20,21]. Due to the orientations of myocardial fibers are different, its movement directions are also different. When the inner layer and outer layer myocardial fibers contract, there is movement in the direction of the long axis, and when the middle layer myocardium contracts, there is movement in the direction of the short axis. GLS, GCS and GRS respectively represent the myocardial deformation in the longitudinal, circumferential and perpendicular directions of endocardium. In addition, GAS is a new parameter^[22,23], which is the integration of GLS and GCS, and it represents the area change rate of endocardium. Longitudinal motion of myocardium is mainly determined by the myocardium fibers in the inner layer, and circumferential are determined by the myocardium fibers in the middle layer^[24,25].

Our study found that the GLS in groups B and C were obviously reduced compared to control group, and the changes were statistically significant. Blood supply to the endocardium comes from the vessels at the end of the coronary artery and studies have shown that change of GLS is dominated by the endocardial myocardium^[26]. So the endocardium is more sensitive to ischemia and hypoxia when the patients with TVD have myocardial ischemia, which means that GLS has changed under normal conditions of LVEF^[27]. If stenosis rate of TVD further aggravates leading to the overload of cardiac and the enlargement of cardiac, the decrease of GLS is more significant. In our study, it was found that the GCS in groups B and C were obviously lower than that in control group($P<0.05$). The circumferential contraction of the short axis of the cardiac is mainly caused by the movement of the middle layer. Generally, myocardial ischemia gradually expands from the endocardium to the epicardium^[28], so when myocardial ischemia and hypoxia occur, the middle layer of myocardial segments are affected, resulting in reduction of GCS. As a specific indicator of 3D-STE, GAS is the integration of GLS of the ventricular long axis and GCS of the ventricular short axis, so the significant reduction of GAS can better assess the cardiac systolic dysfunction in patients with TVD.

GRS represents the thickness of the ventricular wall and the change of the LV volume from the LV short axis view^[29]. In our study, the reduction of GRS in groups B were not statistically significant compared

with group A. It might be because the radial thickening of ventricular wall is the result of the interaction of cross fibers between different myocardial layers and the inner and outer of fibers perpendicular to fiber orientation. Under normal physiological conditions, the systolic thickening ability of ventricular wall mainly depends on the myocardial fibers in the intimal layer. When the contractility of endocardial myocardium is reduced due to ischemia, the outer subepicardial layer contributes to thickening and short-axis function through cross-fiber shortening. In the group C, GRS was obviously decreased compared with the other two groups. It showed that the further development of the disease had affected the middle layer, which was consistent with the research results of Winter et al.^[30]. In addition, the research of Chan et al.^[24] showed that when the degree of coronary stenosis is severe or even myocardial infarction occurs, the peak value of radial strain can show a significant decrease. Therefore, GRS is less sensitive to early identification of myocardial ischemia of TVD.

Diastolic movement of the heart is an active energy consuming process, and the threshold of diastolic function reduction is lower than systolic function^[31]. Therefore, the reduction of diastolic function is earlier than systolic function during myocardial ischemia. Our study evaluated LV diastolic function in line with the guideline issued by the American society of echocardiography in 2016^[32], which proved that the LV diastolic function was decreased in groups B and C, and group C was lower than group B. This is consistent with the results of Rydberg et al.^[33], indicating that LV diastolic function is closely related to the degree of coronary artery stenosis. LVEDP measured by left cardiac catheterization is the gold standard for the diagnosis of LV diastolic dysfunction^[34]. This study found that LVEDP in groups B and C increased, and that in group C was higher than in group B, the difference was statistically significant. At present, there are few studies on the correlation between 3D-STE and LVEDP, and only shin et al.^[35] research confirmed that GLS and GAS were closely related to LVEDP. We results also suggest that the GLS and GAS had significant correlations with LVEDP in group B and group C. In addition, this study found that GCS and GRS also had high correlations with LVEDP in group B and group C. Therefore, 3D-STE has a certain reference value for evaluating LV diastolic function in the patients with TVD.

NT-proBNP is produced by the hydrolysis of proBNP which can produce BNP at the time, and NT-proBNP may be more specific to cardiac activity than BNP^[36]. Studies have confirmed BNP may be actively degraded in peripheral blood, so the test of NT-proBNP is more reliable^[37]. NT-proBNP, as a polypeptide neurohormone, is mainly synthesized and secreted by ventricular myocytes^[38]. In recent years, more and more attention has been paid to the diagnostic and prognostic of BNP in patients with different clinical types of CHD^[39-41]. Some studies have showed the change of serum NT-proBNP closely related to myocardial ischemia and hypoxia. When the systolic function of cardiac is abnormal, the ventricular volume load increases and the ventricular wall is pulled, causing the synthesis and release of NT-proBNP^[42]. Our results showed the level of NT-proBNP was distinctly difference among the three groups. NT-proBNP of group C was highest among of three groups. It was due to the severe stenosis of the TVD result in ischemia of cardiomyocytes and LV systolic dysfunction, which stimulates the synthesized and secreted of NT-proBNP by ventricular myocytes. In group C, the study demonstrated each 3D-STE strain parameter were negatively correlated with NT-proBNP. And the correlation analysis also demonstrated GLS was negatively correlated with NT-proBNP in group B. Therefore, the level of serum NT-proBNP is consistent with the 3D-STE in the evaluation of LV systolic function in patients with TVD.

Study limitations

The present study still existed some limitations. First of all, 3D-STE uses low frame rate to collect real-time three-dimensional full volume images for analysis, which will cause the loss of myocardial motion information and low image resolution. In addition, the image quality is very high. It needs to show the endocardium clearly and then trace it. If necessary, it needs to be manually adjusted, which exists great subjectivity. Furthermore, 3D-STE is not suitable for image acquisition of patients with irregular heart rhythm, and the scanning angle of 3D-STE is narrow, so it is difficult to obtain complete image information for patients with large heart. Finally, we had a relatively small study population, so it is necessary to expand the sample size for further study in the future.

Conclusions

All in all, LV function is closely related to the stenosis degree of TVD. In the early stage of TVD, when the overall left ventricular systolic function is normal, the local left ventricular systolic function has been damaged. As a new technique, 3D-STE can detect the changes of myocardial function earlier in patients with TVD and quantitatively evaluate the global LV function through multiple global strain parameters. This may provide a more effective method for monitoring the change of LV systolic strain and evaluating LV systolic function of TVD without myocardial infarction.
