22

23 Summary

24 The incidence of bovine tuberculosis (TB, caused by *Mycobacterium bovis*) in cattle has been
25 associated with TB in badgers (*Meles meles*) in parts of England. The aim was to identify
26 badger associated *M. bovis* reservoirs in the Edge Area, between the High and Low Risk
27 Areas for cattle TB. Data from badger TB surveys were sparse. Therefore, a definition for a
28 local *M. bovis* reservoir potentially shared by cattle and badgers was developed using cattle
29 TB surveillance data. The performance of the definition was estimated through Latent Class
30 Analysis using badger TB survey data. Spatial units (25 km²) in the Edge Area were classified
31 as having a reservoir if they had i) at least one OTF-W (Officially Tuberculosis Free –
32 Withdrawn) incident in a cattle herd not attributed to cattle movement in the previous two
33 years, ii) more OTF-W incidents than Officially Tuberculosis Free – Suspended (OTF-S)
34 incidents in the previous two years and iii) at least one TB incident (OTF-S or OTF-W) in at
35 least three of the previous seven years. Approximately twenty percent of the Edge Area was
36 classified as having a local *M. bovis* reservoir using the cattle-based definition. Assuming
37 15% TB prevalence in Edge Area badgers, sensitivity for the local *M. bovis* reservoir
38 definition varied from 25.7% (95% Credible Interval (CrI) 10.7 to 85.1 %) to 64.8 % (95% CrI
39 48.1 to 88.0 %). Specificity was 91.9% (CrI 83.6 to 97.4 %). Over ninety percent of the local
40 reservoir was in stable endemic TB areas identified through previous work and its spatial
41 distribution was largely consistent with local veterinary knowledge. Uncertainty in the
42 reservoir spatial distribution was explored through its recalculation in spatial units shifted in
43 different directions. We recommend that the definition is re-evaluated as further data on
44 badger infection with *M. bovis* becomes available.

47 *bovis*

48

49 **1 INTRODUCTION**

50 Bovine tuberculosis (TB) caused by *Mycobacterium bovis* is a persistent insidious disease of
51 cattle to which many other animals including man are susceptible (O'Reilly and Daborn
52 1995). The costs for the control and eradication of TB to the farming industry and to society
53 are considerable (Bennett and Cooke 2006, More et al, 2015, Godfray et al, 2018, Defra
54 2020). Once endemic within a cattle population, TB is difficult to eradicate. This can be due
55 to limitations in diagnostic tests and cattle surveillance. However the presence of a local
56 wildlife host can make a disease particularly intractable. Important wildlife hosts for *M.*
57 *bovis* include the European badger (*Meles meles*) in the UK, Ireland and France, wild boar in
58 Spain, white-tailed deer (*Odocoileus virginianus*) in Michigan USA, the brush tailed possum
59 (*Trichosurus Vulpecula*) in New Zealand and prior to 1997, feral pigs (*Sus scrofa*) in Australia
60 (Aranaz et al, 2004, Bourne 2007, Goodchild et al, 2012, Nugent et al, 2015, More et al,
61 2015, N_I Bhuachalla et al, 2015, VerCauteren et al, 2018). Cattle are an acknowledged
62 reservoir for *M. bovis*. The extent to which infection control in wildlife can affect TB in cattle
63 varies according to factors affecting between-species transmission and the propensity for
64 the wildlife to maintain a *M. bovis* reservoir. In Australia, feral pigs were found to be a
65 spillover or dead-end host but not a reservoir (More et al, 2015). By contrast, the brush-
66 tailed possum and white-tailed deer have been shown to be self-sustaining reservoirs for *M.*
67 *bovis* and sources for TB incidents in cattle (Nugent et al, 2015, VerCauteren et al, 2018).

68 In England, the majority of evidence that the badger is a wildlife host for *M. bovis* comes
69 from the south-west although infected badgers have also been detected in the north
70 (Delahay et al, 2000, 2001, Bourne 2007, Rossi et al, 2021). In Woodchester Park in south-
71 west England, the prevalence of TB in badgers monitored within a 15 km² area increased
72 from 5% to over 30% between 1982 and 2005 (Delahay et al, 2013). Studies of this
73 population and others show persistence of TB in badger social groups and evidence for
74 infection transmission between badgers and cattle (Woodroffe et al, 2005, Goodchild et al,
75 2012, Weber et al, 2013, Benton et al, 2016, McDonald et al, 2018). In these situations,
76 cattle and badgers meet criteria for epidemiologically connected populations maintaining a
77 joint reservoir for *M. bovis* (Haydon et al, 2002). A recent genetic study confirmed
78 transmission of TB between cattle and badgers in Woodchester Park and also showed that

79 the majority of infected badgers in the population examined had acquired infection from
80 other badgers (Crispell et al, 2019). This suggests that there are situations where badgers
81 act as a reservoir, transmitting TB between themselves and spreading the disease to cattle.

82 England is divided into three risk areas for TB (Figure S1). The High Risk Area (HRA)
83 characterised by high TB incidence, frequent testing of cattle and extensive wildlife controls
84 (mainly badger culling but also localised badger vaccination); the Low Risk Area (LRA) with
85 low TB incidence, less frequent testing of cattle and fewer wildlife TB controls; and the Edge
86 Area characterised by highly variable levels of TB in cattle and local variations in disease
87 controls. Cattle TB incidence is generally much higher along the Edge Area's western border
88 with the HRA than along its eastern border with the LRA. For example, county level TB
89 incidence rates in 2019 were more than six times higher in Oxfordshire (23.8 TB incidents
90 per 100 Herd Years at Risk (HYR)), which borders the HRA than in Nottinghamshire (3.4 TB
91 incidents per 100 HYR), which borders the LRA (APHA, 2020a). UK Government policy in the
92 Edge Area has focused on enhanced cattle controls to prevent the establishment of new
93 areas of infection and spread of TB into the LRA (Defra, 2014). Routine field surveillance of
94 cattle for TB using the comparative tuberculin skin test has increased from annually to six
95 monthly in counties with high TB incidence rates (APHA, 2019a). Additional herd and
96 individual animal testing has been introduced where there is heightened risk of TB infection.
97 Infected herds, either Officially Bovine Tuberculosis Free status-Withdrawn (OTF-W) or OTF-
98 Suspended (OTF-S) require at least two rounds of negative tuberculin tests before regaining
99 OTF status. The interferon gamma blood test is also applied in parallel with tuberculin tests
100 in OTF-W herds.

101 In 2015, the Animal and Plant Health Agency (APHA) developed a model to measure the
102 spread and retraction of endemic TB in cattle across the Edge Area (Brunton et al, 2015,
103 Ashton et al, 2015). This has shown retraction in some areas of the Edge Area and spread in
104 others but no generalised retraction over time. The overall incidence rate for TB in cattle in
105 the Edge Area was 9.9 TB incidents per 100 HYR in 2019 and 9.1 in 2018 (APHA 2020a).

106 Surveys of badger populations within England suggest that the density of badgers in the
107 Edge Area is highly variable. Based on broad land class types, badger density is estimated to
108 range from 1-6 km² (Judge et al, 2014; 2017)(Figure 1). In some areas badger densities are

109 comparable with densities in south-west England (HRA) and are considered likely to be
110 sufficient for between-badger infection transmission (G. Smith and A. Robertson personal
111 communication, July 2, 2020). Although data from badgers is relatively sparse, TB confirmed
112 by post-mortem tests has been detected in badgers from the Edge Area (Bennett et al, 2018,
113 Palgrave and Chambers 2018, Sandoval Barron et al, 2018).

114 The independent review of the UK Government's strategy for achieving OTF status for
115 England concluded that it was unclear what drives the spread of TB in the Edge Area
116 (Godfray et al 2018). The review recommended research leading to a better understanding
117 of the prevalence of TB in badgers. The aim of this study was to develop criteria, using
118 currently available data, for defining areas with a *M. bovis* reservoir associated with badgers
119 within the Edge Area for TB in England.

120 **2 MATERIALS AND METHODS**

121 A Working Group was established, which included three veterinary epidemiologists (two of
122 which worked in the field), two analytical epidemiologists, a TB database analyst, a GIS
123 analyst, two statistical modellers and a wildlife ecologist. An iterative discursive approach
124 was taken in the development of the definition of a *M. bovis* reservoir associated with
125 badgers in the Edge Area starting with a review of existing data sources with potentially
126 relevant information.

127 During the development of the reservoir definition, data were mapped as points and/or
128 summarised and mapped on grids of 25 km², 50 km² or 100 km² hexagonal spatial units to
129 enable between area comparisons. We also explored how to represent uncertainty in the
130 reservoir definition.

131 **2.1 Data**

132 Potentially relevant data sources identified included:

- 133 • Ad hoc surveys for *M. bovis* infection in badgers such as badgers found dead
134 after road traffic accidents,
- 135 • *M. bovis* genotype data from infected cattle and badgers in the Edge Area,
- 136 • Test results from surveillance for TB in cattle recorded on the APHA TB
137 management system,
- 138 • Information recorded on Disease Report Forms (DRFs) by APHA veterinarians
139 during investigation and management of TB incidents in cattle herds.

140 **2.1.1 Ad hoc surveys for *M. bovis* infection in badgers**

141 Six surveys of infected badgers conducted between 2014 and 2019 were identified with
142 potentially relevant data parts of from the Edge Area or land in England bordering the Edge
143 (Table 1). The sampling methodology in the surveys was primarily opportunist collection of
144 badgers e.g. found dead due to road traffic accidents. None of the surveys covered the
145 entire Edge Area. Procedures for handling collected badgers and sample processing varied
146 between studies. To improve accuracy the following data were excluded from our analysis:

- 147 1. Studies where detection of *M. bovis* had not been confirmed by isolation of the
148 bacterium and genotyping or spoligotyping
149 2. Samples found to be negative for *M. bovis* where the survey methodology had led to
150 sample degradation, which reduces sensitivity

151 2.1.2 *M. bovis* genotype data from infected cattle and badgers

152 We reviewed maps of the Edge Area with *M. bovis* genotypes from cattle with TB grouped
153 by inferred whole genome sequence (WGS) clade. Where WGS data existed, the spatial
154 distributions of *M. bovis* isolates from cattle were also viewed at different scales of genetic
155 relatedness based on Single Nucleotide Polymorphism (SNP)s. Genetic data from *M. bovis*
156 isolates from badgers could be classified into WGS clades inferred from their spoligotype
157 and VNTR type and mapped. However, the badger data could not be not be analysed using
158 SNP data because these data did not exist. WGS of *M. bovis* isolates was not routinely
159 conducted at APHA prior to 2017 and virtually all the badger data were from earlier studies.

160 2.1.3 Test results from surveillance for TB in cattle

161 Characteristics that could be derived from cattle TB surveillance data and were likely to be
162 indicative of a *M. bovis* reservoir were investigated. Discussions focussed on the following:

- 163 • Evidence for persistent and/or recurrent TB in cattle herds in an area over several
164 years,
165 • Evidence that TB incidents in cattle herds in an area were unlikely to be due to
166 infection brought in by cattle movement,
167 • Evidence for a predominance of TB incidents in cattle herds in an area that had been
168 confirmed by post-mortem tests such as detection of macroscopic lesions typical of
169 TB during slaughterhouse inspection or isolation of the bacterium i.e. more OTF-W
170 incidents than OTF-S.

171 Cattle TB data were summarised to hexagonal spatial units within and bordering the Edge
172 Area (Figure 2). We recognised that differences in the numbers of cattle and herds within a
173 spatial unit would be associated with differences in definition accuracy. However, we
174 wanted to ensure that the level of aggregation did not obscure clusters of infection that
175 could indicate discrete reservoirs (Blangiardo et al, 2020). The 100 km² spatial unit was

176 rejected as too large early on in discussions, and we focused on the resolution provided by
177 25 km² and 50 km² hexagonal spatial units. Badger dispersal distances were also considered
178 and these supported the selection of the smaller spatial unit in our analyses (Table S1).

179 **2.1.3.1 Evidence for persistence of TB in cattle in an area**

180 Evidence for persistence of TB in an area was measured from 2013, which was when annual
181 TB testing for TB in cattle herds was introduced into all counties in the Edge Area. The sum
182 of years when at least one TB incident (OTF-W or OTF-S) had occurred was counted in each
183 25 km² spatial unit over a seven year period (2013-2019). The count was limited to one TB
184 incident per spatial unit per year to reduce possible bias due to differences in testing
185 frequency relating to TB controls e.g. the introduction of six monthly routine surveillance
186 testing in six Edge Area counties between 2015 and 2018.

187 **2.1.3.2 Evidence that cattle TB incidents were not due to cattle movement**

188 Disease Report Forms (DRFs) are completed by APHA veterinarians during TB incidents in
189 the Edge Area for case management and to gather epidemiological information (APHA,
190 2019a). DRFs include an assessment of the level of evidence for different infection sources
191 and transmission (risk) pathways. Evidence that the risk pathway is via cattle movement
192 relies on surveillance records of cattle movements. Genetic evidence of the *M. bovis*
193 genotype in the source and receiving herd is also incorporated where available. The
194 information goes through an auditing procedure annually and the proportion of an incident
195 attributable to different risk pathways is calculated and reported in annual reports (APHA,
196 2020a). For this analysis, TB incidents in the Edge Area where the DRF data showed that the
197 risk attributed to cattle movement was $\geq 75\%$ were removed as not evidence for a badger
198 reservoir.

199 **2.1.3.3 Evidence for a predominance of confirmed TB incidents in cattle**

200 The field veterinary epidemiologists reported that seeding of new infection into cattle herds
201 in an area was often initially characterised by detection of cattle with inconclusive tuberculin
202 skin test results and OTF-S incidents (T. Roberts and S. Frost, personal communication,
203 January 15, 2020). These were followed in time by increased detection of OTF-W incidents,

204 suggestive of an emerging reservoir with wildlife involvement, rather than cattle mediated
205 pathways. It was also noted that culling in the Randomised Badger Culling Trial (RBCT) was
206 associated with a reduction in OTF-W incidents but not OTF-S (Donnelly et al, 2007). This
207 evidence together suggested that OTF-W incidents were more closely associated with
208 presence of infected wildlife than OTF-S. We concluded that evidence for recent
209 predominance of OTF-W over OTF-S incidents would be supportive of a contemporary *M.*
210 *bovis* reservoir.

211 **2.2 Evaluation of a *M. bovis* reservoir based on cattle TB data (the cattle-based definition)**

212 The cattle-based definition for a *M. bovis* reservoir was evaluated in three ways:

- 213 1. The sensitivity and specificity of the definition was calculated through Latent Class
214 Analysis (LCA) comparing the spatial distribution of the reservoir in the Edge Area to
215 data from badger TB surveys.
- 216 2. The spatial distribution of the reservoir in the Edge Area was compared to the
217 distribution of areas classified as having endemic TB using the APHA TB Spread
218 Model (Brunton et al, 2015, Ashton et al, 2015).
- 219 3. The spatial distribution of the reservoir in the Edge Area was evaluated using local
220 veterinary knowledge.

221 **2.2.1 LCA to calculate the performance of the cattle-based definition**

222 Using a Bayesian approach, areas classified as positive or negative for a reservoir according
223 to the cattle-based definition were compared to areas classified as positive or negative
224 according to the *ad hoc* surveys of infection in dead badgers. An area was positive if it had at
225 least one infected badger recorded and negative if all badgers surveyed within it were
226 negative. The approach depended on priors specified for unknown parameters (sensitivities/
227 specificities and prevalence of cells with a reservoir of infection). However, for the present
228 study there was no strong view on the expected value of the unknown parameters, and so
229 uninformative priors were used; uniform distributions represented by beta distributions
230 with both parameters equal to 1 (more detail is provided in the supplement).

231 The assessment of the sensitivity of the cattle-based definition took account of the
232 sensitivity of post-mortem detection of *M. bovis* infection in badgers and the number of
233 badger samples (Figure 3). Evaluation of the specificity was more problematic because of an
234 absence of empirical data showing the relationship between detecting a negative badger
235 and all badgers in an area being negative for TB. There was agreement that the detection of
236 an infected badger was strong evidence for TB within the local badger population, but not
237 necessarily that TB was endemic in that population. The precise estimate for specificity for a
238 local reservoir was therefore model determined. LCA was conducted for scenarios for high
239 (30%), medium (15%) and low (7.5%) *M. bovis* prevalence in badgers. These were based on
240 published estimates of TB prevalence in badgers anticipated in the Edge Area (Bourne 2007,
241 Delahay et al, 2013, Sandoval Barron et al 2018).

242 The Edge Area was partitioned into six areas that we estimated as having different risks for a
243 *M. bovis* reservoir (Table 2). The performance of the cattle-based definition was estimated
244 separately for these areas and for different TB prevalence to accommodate heterogeneity.

245 **2.2.2 Comparison of areas classified as having a reservoir using the cattle-based definition** 246 **to areas classified as having endemic TB using the TB spread algorithm**

247 A previously developed method for measuring spatial spread and retraction of TB classifies a
248 cattle farm with TB, as being in an area with endemic TB if it is located within seven
249 kilometres of the third nearest OTF-W incident within a two year time period (Brunton et al.,
250 2015, Ashton et al., 2015). To improve specificity, we modified this algorithm for the current
251 study by excluding TB incidents where the incident had been predominantly attributed to
252 cattle movement based on DRF information. Edge Area classified as endemic using the
253 spatial spread definition was compared to areas classified as having a *M. bovis* reservoir
254 using the cattle-based definition.

255 **2.2.3 Evaluation of the cattle-based definition using local veterinary knowledge**

256 Working group veterinary field epidemiologists (S. Frost and T. Roberts) with detailed
257 knowledge of the disease situation in the Edge Area were asked to make a qualitative
258 assessment of the validity of the local reservoir location using large scale (1:100,000) maps.

259 A detailed picture has been developed over the last few years by APHA vets of where local
260 reservoir of infections are likely to be in the Edge Area (APHA, 2020b). A range of data
261 sources including DRFs have been used to inform local knowledge. For example, since mid-
262 2017, the WGS data has provided more robust evidence for local wildlife reservoirs where
263 there has been high genetic relatedness between isolates in local geographical areas, and
264 cattle movements and contiguous contact between herds have been ruled out as methods
265 of local infection spread. Confirmation of TB in small numbers of isolates from camelids,
266 pigs, goats and zoo collections as well as wild deer and badger isolates have complemented
267 and supported the local picture over time.

268 **2.2.4 Uncertainty**

269 To account for possible wildlife spread from the identified reservoir, the addition of a buffer
270 around areas defined as having a *M. bovis* reservoir was considered.

271 Possible bias due to spatial heterogeneity was explored with the presence or absence of a
272 reservoir recalculated for spatial units shifted in cardinal and inter-cardinal directions. A
273 slight shift in position of an individual spatial unit could change the herds within a spatial
274 unit's boundaries and therefore the outcome of the reservoir definition for that locality. The
275 shape of the unit was also considered with both hexagons and circles evaluated.

276 A final map showing the location of the reservoir was generated that provided an indication
277 of levels of uncertainty due to spatial unit location. Presence or absence of a local reservoir
278 using the cattle-based definition was calculated for circular 25 km² spatial units on a regular
279 grid with the centroids two km apart. This was then re-calculated for the spatial unit shifted
280 two km in four directions.

281 **3 RESULTS**

282 There were insufficient data TB data from badgers and/or WGS data from badgers to
283 develop a definition for a reservoir based on badger data. Therefore, a definition for a *M.*
284 *bovis* reservoir was developed using cattle TB surveillance data. This definition is hereafter
285 referred to as a 'local reservoir', and identifies areas where there is a potential localised
286 reservoir in cattle and/or badgers.

287 Genetic data from TB infected cattle, although considerably more abundant than for
288 badgers, were insufficient to develop a model that would identify incidents due to local
289 reservoirs in the Edge, potentially shared by badgers, as opposed to common sources from
290 cattle that had moved into the area. Infected badgers and cattle shared the same inferred
291 WGS clades in some areas of the Edge Area but not all. However, a clade can include isolates
292 that differ by as much as 50 SNPs and clades could not be used to define localised areas of
293 transmission.

294

295 **3.1 A cattle-based definition for a local reservoir of *M. bovis* infection**

296 An area was classified as having a local *M. bovis* reservoir if it met all of the following
297 criteria:

- 298 1. At least one TB incident (OTF-S or OTF-W) in a cattle herd in at least three of the
299 previous seven years (2013-2019);
- 300 2. At least one OTF-W incident in a cattle herd not attributed to cattle purchasing in the
301 previous two years (2018 or 2019).
- 302 3. More OTF-W incidents than OTF-S incidents in cattle herds in the previous two years
303 (2018 or 2019).

304 Approximately twenty percent (230/1177) of the 25km² hexagonal spatial units in the Edge
305 Area were classified as having a local *M. bovis* reservoir using the cattle-based definition
306 (Figures 4 and 5, APHA, 2021). More spatial units were classified as having a local reservoir
307 in the western part of the Edge Area than in the east. A small number of spatial units were
308 classified as having a local reservoir in Leicestershire and East Sussex and isolated locations

309 elsewhere. Applying the same definition to 50 km² spatial units showed a similar spatial
310 distribution of putative local reservoirs for *M. bovis* infection (Figure S2).

311 Spatial units with more cattle herds were statistically significantly more likely to be classified
312 as having a local *M. bovis* reservoir. For example, 25 km² hexagonal spatial units classified as
313 having a local reservoir had a median of nine (inter-quartile range (IQR) 5 to 18) cattle herds
314 in 2018 and 2019 whereas spatial units without a reservoir had a median of four (IQR 2 to
315 8). The median number of cattle herds per 25 km² and 50 km² hexagons for 2018 and 2019
316 were seven (IQR 4 to 12) and 12 (IQR 8 to 20) respectively (detail provided in the
317 supplement Table S2).

318 A buffer of one hexagonal spatial unit was added to the putative boundary of local
319 reservoirs to account for uncertainty in the boundary and potential additional TB spread due
320 to ranging by badgers (Figure 5). This increased the percentage of Edge Area associated with
321 a local reservoir (324/1177 25 km² spatial units).

322 **3.2 Results from assessments of the performance of the cattle-based definition**

323 **3.2.1 LCA comparing the cattle-based definition to the badger TB survey data**

324 The sensitivity of the cattle-based definition generally increased with the estimated badger
325 TB prevalence. The sensitivity estimates were most often highest for Cheshire (area
326 category 1), and the six monthly testing areas other than Cheshire (area category 2), slightly
327 lower for the HRA border (area category 3) and lowest for north-east counties and East
328 Sussex (area category 4) (Table 2). The definition could not be evaluated in the group of
329 similar southern Edge Area counties (area category 5) and the LRA because there were none
330 or too few badger TB data available.

331 The specificity estimate for the cattle-based definition in the LCA was highest for a 15%
332 badger TB prevalence, but lower than the specificity of the badger data (Table 3). Specificity
333 was lowest for badger TB prevalence of 7.5%. Similar trends were observed in an LCA
334 applied to 50 km² spatial units (results not shown).

335

336 **3.2.2 Comparison of the reservoir defined by the cattle based definition to areas with**
337 **endemic TB defined using the TB spread algorithm**

338 There was extensive overlap between areas defined as having a local *M. bovis* reservoir
339 using the cattle-based definition, and areas defined as having endemic TB using the
340 algorithm for calculating TB spread (Figure S3). Ninety-one percent (209/230) of spatial units
341 in the Edge Area that were classified as having a local reservoir were located within areas
342 defined as having endemic TB using the spread model.

343 Table 4 shows the percentage of spatial units classified as positive within and bordering the
344 Edge area using the cattle-based definition, the badger TB survey data and the TB spread
345 model. Overall, the TB spread model classified a higher proportion of spatial units as
346 positive according to its definition than the other methods according to theirs, with the
347 badger TB survey data classifying the lowest proportion. The proportion of positive badger
348 TB survey spatial units was greatest in areas 1 and 3, whereas it classified far fewer positive
349 spatial units than the cattle based definition in area 2.

350 **3.3.3 Evaluation of the cattle-based definition using local veterinary knowledge**

351 The working group field veterinary epidemiologists found that there was overall, a good
352 match between areas classified as having a local *M. bovis* reservoir based on the cattle
353 definition and the areas currently assessed locally by APHA veterinarians as having endemic
354 infection in badgers (detail provided in the supplement). In Cheshire for example, the map
355 of the local reservoir agreed very well with local expert knowledge. Additionally the map
356 showed two areas of reservoir (in the north east and north west), which had been
357 highlighted by veterinary field epidemiologists as likely areas of emerging endemicity and of
358 increased risk of infection spread to the neighbouring LRA. There were some
359 inconsistencies. The map of a local associated reservoir of infection in Derbyshire agreed in
360 part with local knowledge. There were areas e.g. from Buxton in the north to Swadlincote in
361 the south considered to have emerging endemicity not covered by the local reservoir
362 defined using the cattle-based definition. There was a spatial unit that contains a large
363 water body (Carsington Water), which was not classified as having a reservoir of infection
364 but where local knowledge indicates a strong suspicion of established endemicity.

365

366 **3.4 Uncertainty**

367 The final map shows the presence or absence of a local reservoir for circular 25 km² spatial
368 units two km apart (Figure 6). Each grid-point was over-lapped by five circular 25 km² spatial
369 units. The highest certainty for a local reservoir at a grid point was when all five of its
370 circular spatial units were classified as having a reservoir. The lowest level was when only
371 one spatial unit at a grid point was classified as having a reservoir. A buffer 2.8 km in width
372 was also applied to the new boundary of the reservoir to incorporate potential additional TB
373 spread by badgers. The width (2.8 km) was narrower than the buffer on the original map
374 (5.6-6.2 km) (Figure 5). This was because some of the uncertainty in the boundary to the
375 reservoir had been addressed in the final map. The area of the local reservoir had been
376 extended through its recalculation across shifted spatial units.

377 Comparison of the spatial distribution of the local *M. bovis* reservoir in the original map to
378 the reservoir regenerated by the different shifts in the final map showed small differences in
379 its spatial distribution and a very high degree of overlap (Figure S4). The new reservoir
380 boundaries were for the most part within the external boundary to the buffer to the
381 reservoir on the original map. However, some isolated spatial units were classified as
382 having a local reservoir in the final map that were not detected in the original map. None of
383 the new areas classified as having a reservoir incorporated a grid point with five levels of
384 evidence.

385 **4 DISCUSSION**

386 A definition for a local *M. bovis* reservoir has been developed using cattle TB surveillance
387 data. It identified areas likely to have a reservoir associated with cattle that may be shared
388 with other epidemiologically connected populations. Eradication of disease is challenging
389 where there is evidence for substantial infection in wildlife and transmission between
390 wildlife and domesticated animals (Livingstone et al., 2015). A robust definition requires
391 comprehensive and accurate test data from susceptible populations and environmental
392 sources with transmission supported by molecular genetic evidence from pathogen isolates.
393 However, obtaining such data over large areas, particularly from wildlife, can be extremely
394 difficult and expensive. This work shows that a definition can be developed that may have
395 practical value in absence of comprehensive data from wildlife.

396 The findings indicate that local reservoirs for *M. bovis* are found in some parts of the Edge
397 Area for TB in England but not throughout the entire area. Haydon and colleagues proposed
398 that a disease reservoir can exist in one or more epidemiologically connected populations or
399 environments where a pathogen can be permanently maintained and transmitted to other
400 populations (Haydon et al, 2002). Our definition is dependent on cattle TB surveillance data
401 being a reliable sentinel for infection in badgers. This approach has been used elsewhere
402 (Murphy et al 2011), and there is considerable evidence of transmission between cattle and
403 badgers (Woodroffe et al, 2005, Goodchild et al, 2012, Weber et al, 2013, Benton et al,
404 2016, McDonald et al, 2018, (Crispell et al. 2019, Rossi et al. 2021). Based on this evidence
405 we have assumed that locations with higher levels of TB in cattle are more likely to have
406 infection present in badgers, than areas with little or no TB in cattle.

407 The first criterion for the local reservoir definition was evidence for repeated TB incidents in
408 local cattle in an area over a period of seven years. The threshold of 'in at least three years
409 with a TB incident' attempted to account for possible bias due to both a lower frequency of
410 incidents due to persistent incidents lasting for 18 months or more and a higher frequency
411 due to more frequent TB tests in some areas relative to others.

412 The second criterion required evidence of recent TB incidents in an area that were unlikely
413 to be due to cattle moving into the area. This relied on data collected by veterinary field
414 epidemiologists during DRF risk pathway assessments. These assessments incorporate

415 information from farm surveys, cattle movement records and *M. bovis* genotype data,
416 where available. Pathways are given a score reflecting the level of evidence and certainty in
417 the pathway. In this study we only used audited DRF data produced for annual TB
418 Epidemiology reports. However at the time of the audit, some TB incidents were still
419 ongoing and provisional risk pathways can be revised by the end of an incident. This will
420 have introduced a misclassification bias, which is difficult to eliminate where DRF data from
421 recent TB incidents is required and some incidents will be ongoing.

422 The third criterion was a predominance of OTF-W (confirmed by post-mortem TB tests)
423 incidents over OTF-S (unconfirmed). Seventy-five percent of spatial units in the Edge Area
424 with more OTF-W incidents than OTF-S were classified as having a reservoir. The positive
425 predictive value of TB tests will increase as background TB prevalence increases. Anecdotal
426 evidence from veterinarians working in TB control suggested an increase in the OTFW OTFS
427 ratio as infection becomes established in the local wildlife. However, the criterion could also
428 relate solely to increased transmission and residual infection within local cattle herds,
429 particularly large herds.

430 The performance of the local *M. bovis* reservoir definition was assessed using LCA. The LCA
431 methodology was adapted from previously published models (Branscum et al., 2005) to
432 allow for the sensitivity of the badger TB data to detect infection in badgers to vary between
433 25 km² spatial units according to the number of badgers sampled. The disadvantage of this
434 approach was that it requires an estimate of the infection prevalence in spatial units where
435 there were limited data. The model itself could be used to infer the sensitivity of the badger
436 TB data and the mean infection prevalence in badgers by including them as an unknown
437 parameters, but this would result in too many unknown parameters.

438 Local reservoir specificity of the cattle-based definition was estimated in the LCA to be over
439 90% but sensitivity estimates varied widely. The lack of contemporary badger TB data may
440 have reduced the reliability. Assuming 15% TB prevalence within badgers in the Edge Area,
441 sensitivity for the local *M. bovis* reservoir varied from 25.7 % (95% Credible Interval (CrI)
442 10.7 to 85.1 %) to 64.1 % (95% CrI 48.1 to 88.0 %). Specificity was 91.9% (CrI 83.6 to 97.4 %).
443 Sensitivity estimates from Cheshire were probably most reliable since more badger surveys
444 had been conducted in this county than any other and cattle herds are found in most parts

445 of the county. Central estimates for the sensitivity of the cattle-based definition in Cheshire
446 ranged from 64.8 to 73.6%.

447 The power of the badger data was limited by the low number of samples obtained through
448 opportunist surveys, especially in some areas. This meant that we were unable to infer
449 infection prevalence from the data but rather had to look at scenarios with assumed badger
450 infection prevalence. The low prevalence scenario may be inappropriate for some areas.
451 For example, the mean sensitivity of badger data (assuming an infection prevalence of 7.5%)
452 in badgers is around 14% (Table 3), whereas for area 1 (Cheshire) 33% of the badger
453 samples were positive (Table 4). The model reconciles this by assuming many of the badger
454 positive 25 km² spatial units in Cheshire are false positives, which also results in a low
455 specificity estimate for the cattle definition in this scenario (Table 3). Given that Cheshire is
456 an area with high cattle density, it might be expected to be one of the better performing
457 areas for the cattle definition, suggesting that the low prevalence assumption is not
458 appropriate for this area.

459 The distribution of areas defined as having a local reservoir in this analysis and areas defined
460 as having stable endemic TB using a model for TB spread algorithm overlapped. This was
461 unsurprising since both models used cattle TB data (Brunton et al, 2015, Ashton et al, 2015).
462 However, the distribution of the local reservoir showed more spatial heterogeneity than the
463 distribution of the endemic areas and covered less of the Edge Area. The TB spread model
464 took account of distance between incidents whereas distance was not explicitly included in
465 the cattle-based definition for a local reservoir although incidents were summarised to a
466 spatial unit.

467 The distribution of the local reservoir was reviewed by veterinary epidemiologists with local
468 knowledge. Although developed over a long period of time, local knowledge is still
469 essentially cattle-based. As with the cattle-based definition, where cattle density is low,
470 uncertainties in local knowledge is higher. The certainty associated with emerging areas of
471 local reservoir is generally lower than for older established areas. However, experience
472 indicates that such areas generally continue to develop and expand with time and as more
473 data are collected, this has supported earlier indications of local reservoirs.

474 Our aim was to select as small a spatial unit as reasonably possible to increase our ability to
475 detect local variations (Malleson et al, 2019, Blangiardo et al, 2020). If the spatial unit had
476 been too large and within-area variability substantial, our results could suffer from false
477 negative observations as areas with a reservoir areas are aggregated with areas without a
478 reservoir. However a spatial unit that is too small increases uncertainty where data are
479 sparse and more liable to misclassification biases e.g. the geo-coordinates of farms may be
480 imprecise indicators for the location of cattle herds. By shifting the centroids to the spatial
481 unit and recalculating the definition for presence or absence of a reservoir we increased the
482 geographical area (and therefore the information) associated with any grid point whilst also
483 showing where the data were most consistent. Areas defined as having a local reservoir
484 were shown in five levels relating to the consistency of evidence (the number of times) that
485 an area was classified as having a local reservoir. A 2.8 km wide buffer was also added
486 around the local reservoir border to indicate the range of possible TB spread from the
487 reservoir. A straight line distance of 2.8 km encompasses approximately two badger social
488 group territories in the LRA (G.C. Smith, personal communication, March 11, 2021).

489 The cattle-based definition is likely to be a less precise predictor for local *M. bovis* reservoirs
490 where there are few or no cattle herds, despite the addition of a buffer to take account of
491 infection transmission in the absence of cattle. The definition is likely to be a more sensitive
492 to local reservoirs maintained jointly between cattle and badgers and less sensitive to
493 reservoirs maintained independently of cattle. However, there are contradicting views
494 regarding whether badgers can be an independent *M. bovis* reservoir differ (N_I Bhauachalla
495 et al, 2015, Godfray et al, 2018).

496 Our cattle-based definition may also indicate joint local reservoirs between cattle and non-
497 badger wildlife. Both wild deer and boar infected with TB have been detected in England
498 and Wales. Boar are rarely sighted and research suggests that deer are less important than
499 badgers for TB in cattle, and are only likely to be reservoir hosts in areas of high deer density
500 (Ward et al. 2009, Ward and Smith 2012). Genetic analyses of *M. bovis* isolates from
501 badgers and cattle shows that the level and the predominant direction of transmission
502 between cattle and badgers varies between areas (Crispell et al. 2019, Rossi et al. 2021).
503 Residual infection (e.g. undisclosed infected cattle and an *M. bovis* contaminated
504 environment) may also contribute to the local reservoir. In the longer term, more robust

505 evidence should be sought with analysis of transmission pathways in areas of low and high
506 cattle/wildlife density.

507 This work increases the information available for locally focused TB management. A novel
508 approach was taken to define the areas because of the scarcity of direct evidence for
509 presence or absence of TB in badgers. The evidence suggested that local *M. bovis* reservoirs
510 predominate on the western border of the Edge Area with the HRA. However, reservoirs
511 were also detected in other areas including to the east near the LRA border in Leicestershire
512 and Northamptonshire. We suggest this definition is re-evaluated when further data on
513 badger infection becomes available. Even within a given species or country, the role that
514 wildlife plays in TB transmission is likely to vary with variations in population density,
515 disease prevalence, as well as other ecological factors that change over time.

516 **Acknowledgments**

517 The methodology was reviewed midway by Jo Wheeler, Paul Upton and Lucy Brunton and
518 we thank them for their comments. We also thank James McCormack for his useful
519 comments throughout the work and Phil Hogarth for his useful comments on the final draft
520 of the manuscript. Dan Brown and Catherine Wood are thanked for help with the final
521 maps and their presentation. We thank Emily Rimap for checking reference. We are most
522 grateful to the teams who undertook badger surveys and/or collected badger samples.

523 **Funding**

524 Funding for the project was provided by Defra (project EA3131).

525 **Authorship**

526 All authors contributed to discussions that led to the development of the cattle-based
527 definition. MA conducted the Latent Class Analysis. AP extracted cattle surveillance data
528 from the APHA management system and in conjunction with SD and SA conducted the
529 descriptive data analyses. SA undertook the GIS analyses and produced all maps during the
530 development phase and also produced the final maps. KH helped with presentation of
531 maps. TR and SF reviewed the distribution of the local reservoir against their local field
532 knowledge of TB in the Edge Area. KH undertook the literature review of badger dispersion
533 distances with help from AR. All authors reviewed and commented on the final manuscript.
534 SD was the project leader and wrote the first draft of the manuscript.

535 **Conflict of Interest Statement**

536 None of the authors have a conflict of interest in relation to this work.

537 **Data sharing**

538 The underlying individual data are not publicly available due to privacy restrictions to
539 prevent identification of farms or individuals.

540 **Ethics statement**

541 The authors confirm that the ethical policies of the journal, as noted on the journal's author
542 guidelines page, have been adhered to. The work used pre-existing data.

678 **Table 1. Samples from opportunist badger TB surveys within and bordering the Edge Area**

Survey	Year	Negative for TB	Confirmed positive for TB
North (EN1617) Bennett et al, 2018	2016/2017	569	33
South (ES1617) Palgrave and Chambers 2018	2016/2017	0 ^a	3
Cheshire (EC1415) Sandoval Barron et al, 2018	2014/2015	74	20
HRA border (EOS2016) ^b	2016	0 ^c	8
Hotspot Leicester (HTSP 2019)	2019	9	2

679 All the surveys used culture to grow colonies of MTBC (*Mycobacterium Tuberculosis* Complex),
 680 and confirmation of *M. bovis* was achieved through Spoligotyping (genotyping by spacer
 681 oligonucleotide patterns). †Samples from badgers obtained from licensed culling. ^a90 and ^c84
 682 samples were excluded because of reported degradation of the samples. All samples were from
 683 within the Edge Area and border areas within England (Figure 1). The border area extended up
 684 to 14 km beyond the Edge Area boundary. Its precise width was dependent upon where
 685 hexagonal spatial units crossing the Edge Area boundary are bisected.

686 **Table 2. Edge Area and border categories for a *M. bovis* infection reservoir in badgers**

Area category	Description	Rationale
1	Cheshire.	Higher prevalence of <i>M. bovis</i> infection in badgers anticipated. Cattle in most of the county were subject to six monthly TB surveillance testing since 2015. The county has had more surveys for <i>M. bovis</i> infection in found dead badgers than any other county in the Edge.
2	Six monthly TB testing areas minus Cheshire (Warwickshire, Oxfordshire, part of Berkshire, part of Hampshire and part of Derbyshire).	Higher prevalence of <i>M. bovis</i> infection in badgers anticipated. Cattle in these areas were subject to six monthly TB surveillance testing since 2018.
3	HRA border abutting the western boundary of the Edge Area. This area starts from the south-coast and ends with a northern boundary to Clwyd.	Higher prevalence of <i>M. bovis</i> infection in badgers anticipated. Endemic infection in cattle and badgers probable. Cattle in these areas were subject to annual TB surveillance testing up to September 2020.
4	East Sussex and north east Edge Area counties including part of Derbyshire, Nottinghamshire, Leicestershire and Northamptonshire	The distribution of a <i>M. bovis</i> infection reservoir is thought to be heterogeneous in these counties. All cattle herds were subject to annual TB surveillance testing.
5	Edge Area counties of Buckinghamshire, part of Berkshire and part of Hampshire.	The prevalence of <i>M. bovis</i> infection in badgers is thought likely to be similar and low in these counties. Cattle herds were subject to annual TB surveillance testing.
6	LRA border to the east and north of the Edge Area from the south coast ending at the northern border with Clwyd in Wales.	Lower levels of <i>M. bovis</i> infection in cattle and anticipated in badgers. Cattle in these areas were subject to four yearly testing.

687 Data for spatial units were assigned to the area category that contained the greatest proportion
 688 of their land e.g. Data for a spatial unit with 51% of land in Area Category 1 and 49% of land in
 689 the Area Category 2 would be assigned to Area Category 1. Areas are within the Edge Area and
 690 border areas within England. The border area extends up to 14 km beyond the Edge Area

691 boundary. Its precise width is dependent upon where hexagonal spatial units crossing the Edge
692 Area boundary are bisected.

693

694 **Table 3. Latent Class Analysis estimates for the performance of the cattle-based definition**
 695 **for a local *Mycobacterium bovis* reservoir in 25 km² hexagonal spatial units**

Parameter	Area category	Assumed mean badger infection prevalence		
		7.5%	15%	30%
Se_c	1. Cheshire	73.6 (50.2, 98)	64.8 (48.1, 88)	71.3 (55.5, 89.4)
Se_c	2. 6 monthly testing areas minus Cheshire	42.9 (36.2, 57.1)	63.0 (42.5, 94.4)	74.8 (56.6, 94.5)
Se_c	3. HRA border	76.6 (50.8, 98.7)	54.9 (41.6, 94.5)	51.7 (41.2, 76.9)
Se_c	4. Edge northeast & East Sussex	7.8 (5.1, 11.2)	25.7 (10.7, 85.1)	30.7 (14.3, 84.6)
Sp_c	All	60.2 (33.3, 86.9)	91.9 (83.6, 97.4)	88.9 (81.7, 94.7)
Sp_b	All	64.5 (36.3, 85.6)	94.1 (87.6, 99.5)	96.5 (90.6, 99.8)
π_1	1. Cheshire	55.8 (33.6, 87.2)	78.3 (54.5, 97.7)	67.4 (50.1, 85.4)
π_2	2. 6 monthly testing areas minus Cheshire	90.5 (65.8, 99.5)	61.4 (39.8, 91.5)	50.4 (38, 66.6)
π_3	3. HRA border	55.7 (40.6, 82.9)	80.1 (45.7, 99.1)	85.0 (56.7, 99.2)
π_4	4. Edge northeast & East Sussex	95.4 (73.4, 99.8)	23 (6.7, 49.6)	17.3 (6.1, 31.1)

696 Se_c =Sensitivity of the cattle-based definition. Sp_c = Specificity of the cattle-based definition.

697 Sp_b = Specificity of the Badger TB data. π_{\square} = TB Prevalence. From a two test model including the
 698 cattle-based definition and badger TB test data. Sensitivity is the percentage of spatial units
 699 classified as having a reservoir using the badger TB survey data that were classified as having a local
 700 reservoir. Specificity is the percentage of spatial units classified has not having a reservoir using
 701 badger TB survey data that were negative for a local reservoir using the cattle-based definition. Data
 702 for hexagonal spatial units were assigned to the area that contained the greatest proportion of their
 703 land. Further detail is in the supplement.

704

705

706 **Table 4. Number of 25 km² spatial units with a local *Mycobacterium bovis* reservoir, at**
 707 **least one badger with confirmed TB and with endemic TB in the Edge Area and border**

Area category	Number of hexagonal spatial units positive in an area (% of spatial units positive in an area)		
	Cattle-based definition	Badger TB survey	TB spread model
1. Cheshire	51 (52.3)	19 (32.8)	74 (76.3)
2. 6 monthly testing areas minus Cheshire	122 (39.7)	12 (13.5)	240 (78.2)
3. West Border (HRA)	109 (46.4)	8 (42.1)	179 (76.5)
4. North-eastern counties & East Sussex	31 (7.8)	12 (7.8)	69 (17.4)
5. Other Southern counties/part counties	4 (1.8)	0 (0)	23 (10.3)
6. North and East Border (LRA)	3 (0.8)	0 (0)	7 (1.8)

708 Positive indicates a 25 km² hexagonal spatial unit classified as having a local *M. bovis* reservoir, with
 709 at least one badger with confirmed TB or classified having endemic TB according to the cattle-based
 710 definition, Badger TB survey data or the TB spread model respectively. Denominators differ. Both the
 711 cattle based definition and the TB spread model were calculated using cattle TB surveillance data
 712 throughout the Edge Area and border (extending up to 14 km from the boundary of the Edge Area)
 713 in England and including a total of 1,645 hexagonal spatial units. Badger TB survey data was from six
 714 surveys conducted in different parts of the Edge Area and data from badgers was available for a total
 715 of 323 hexagonal spatial units (Table 1 and Figure 1).
