## Key Points:

- Early space-borne observations (SAGE instruments) cannot be used for ATAL evolution studies, contrary to previous claims.
- SAGE lacks sufficient data in the tropics and an effective cloud capture method to reliably detect or exclude the presence of ATAL.
- First model simulations indicate an ATAL signal, without volcanic influence, in 1979 and 1980.

**Abstract**

An enhanced aerosol layer, known as the Asian Tropopause Aerosol Layer (ATAL), has been observed within the seasonal Asian monsoon anticyclone (AMA) since the late 1990s. Given the apparently abrupt appearance of this layer based on observations, it has been speculated that it originates from increasing human made emissions in Asia. However, the ATAL confinement is a result of a dynamical feature and does not purely consist of human made components. We herein investigate the possible existence of an ATAL earlier than the late 1990s. We exploit earliest possible, high quality space-based aerosol observations from Stratospheric Aerosol and Gas Experiment, or SAGE (1979-1981), SAGE III/ISS (2017, ongoing) and revisit SAGE II (1984-2005) data analysis. We find that seasonal averaged solar occultation aerosol measurements (past and present) can neither be used to exclude the existence of the ATAL, nor to infer a significant trend. However, first CAM5-MAM7 simulations indicate the presence of an ATAL signal for the tested years 1979 and 1980, with a human made component. We hypothesize that the human made component of the ATAL likely occurred since at least the 1970s, while the natural ATAL component (e.g. from dust) has always existed. Extended simulation based ATAL evolution studies are therefore the most reliable source for early ATAL investigations.

**Plain Language Summary**

An enhanced aerosol layer in the Upper Troposphere and Lower Stratosphere (UTLS), known as ATAL (Asian Tropopause Aerosol Layer), was discovered during the seasonal Asian monsoon. Initial observations from space-borne aerosol data suggested its first appearance in the late 1990s. However, our study reveals that the data set used (from SAGE instruments) is inadequate for ATAL evolution studies and to conclusively determine its existence. The limited sampling within the Asian monsoon region and cloud filtering procedure do not provide sufficient data points for definitive conclusions. Nevertheless, the dynamical structure leading to an ATAL has always been present, leading us to hypothesize that the non-human-made ATAL component has existed previously. Additionally, our first model simulations for 1979 and 1980 indicate the presence of an ATAL.

**1 Introduction**

During Northern hemispheric summer the Asian monsoon is associated with the rainy season (June to September). The large scale monsoon convection lifts continental, polluted air masses from the boundary layer to the upper-troposphere/lower-stratosphere (UTLS), where they are trapped within the dynamical boundaries of the Asian monsoon anticyclone (AMA). Deep convection sources for the air within the AMA takes mainly place at the foot hills of the Himalayas and the Sichuan Basin (e.g. Pan et al., 2016; Yuan et al., 2019; Fadnavis et al., 2013). This results in an enhancement of tropospheric trace gases (e.g. Santee et al., 2017) and aerosols (e.g. J.-P. Vernier, Thomason, & Kar, 2011; Yu et al., 2015; Bossolasco et al., 2021) within the AMA. The enhanced aerosol layer observed in the AMA is called the Asian Tropopause Aerosol Layer (ATAL). The ATAL was first reported by J.-P. Vernier, Thomason, and Kar (2011) with satellite-based data (i.e., CALIOP: Cloud-Aerosol Lidar with Orthogonal Polarization). Since then, the existence of the ATAL was detected with multiple other satellite instruments (Stratospheric Aerosol and Gas Experiment, SAGE II: J.-P. Vernier et al. (2015) and Thomason and Vernier (2013), SAGE III/ISS and Ozone Mapping and Profiler Suite, OMPS: Kloss et al. (2019); CRyogenic Infrared Spectrometers and Telescopes for the Atmosphere, CRISTA: Höpfner et al. (2019) and in situ measurements (J.-P. Vernier et al., 2018; Brunamonti et al., 2018; Höpfner et al., 2019; Mahnke et al., 2021; Appel et al., 2022; H. Vernier et al., 2022). Multiple model studies have investigated the composition, source regions and evolution of the ATAL (e.g. Fadnavis et al. (2019)). Based on simulations, which do not

76 account for the locality of convection, main boundary layer source regions have been found  
 77 at the Tibetan Plateau, southwest China, southeast Asia and the western Pacific (e.g.  
 78 Vogel et al., 2015; Fairlie et al., 2020). However, source regions may vary even within  
 79 each monsoon season, strongly influencing the strength of the ATAL (Vogel et al., 2015).  
 80 The variability of the strength of the monsoon dynamics is also closely related to the day-  
 81 to day distribution variability of enhanced trace gases and aerosol in the AMA (e.g. Lau  
 82 et al., 2018; Hanumanthu et al., 2020; Fadnavis et al., 2017).

83 The only attempt to investigate the first buildup and year-to-year evolution of the ATAL  
 84 was made by J.-P. Vernier et al. (2015) (V15), using satellite observations by SAGE II  
 85 and CALIOP ranging back to 1996. It was concluded, and has been widely accepted af-  
 86 terwards by the scientific community, that the ATAL first appeared in 1998, likely re-  
 87 sulting from increasing anthropogenic SO<sub>2</sub> emissions in Asia. However, some doubts re-  
 88 main on why the ATAL would first appear by 1998. Multiple results and arguments point  
 89 to a possible existence of the ATAL prior to the 1990s:

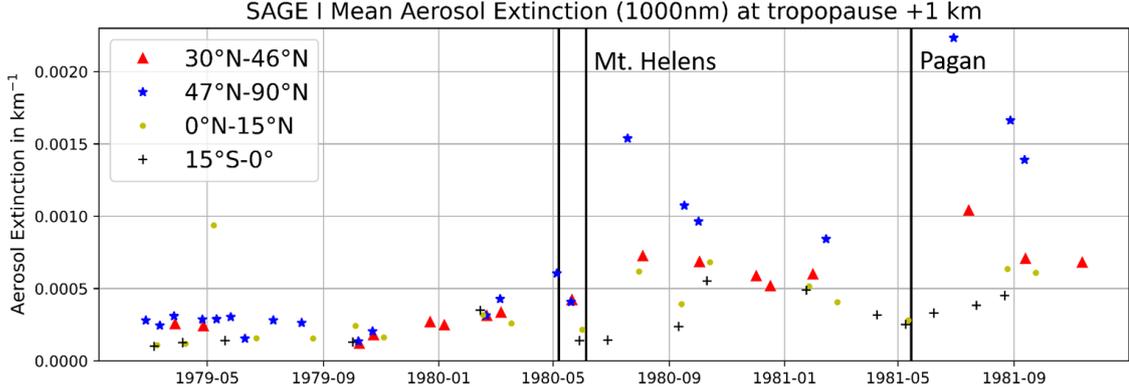

- 90 1. Model studies suggest that the ATAL aerosol is diverse in composition and not  
 91 completely human-derived: Simulations show multiple types of aerosols within the  
 92 ATAL including mineral dust, organic aerosol, nitrate, sulfate, and ammonium aerosol,  
 93 without an exclusive human-derived component (Ma et al., 2019; Yuan et al., 2019;  
 94 Fairlie et al., 2020; Bossolasco et al., 2021). A model study by Neely et al. (2014)  
 95 shows that the ATAL might also exist without any emission contributions from  
 96 Asia. Though, they also show that, for their model setup, without global anthro-  
 97 pogenic emissions there would not be an ATAL layer. The model set up in Neely  
 98 et al. (2014) does not consider ammonium chemistry.
- 99 2. Höpfner et al. (2019) detected ammonium nitrate aerosols within the AMA in 1997,  
 100 using archived satellite data (their Figure 1 with CRISTA-data). For the year 1997,  
 101 space-borne data analysis in V15 did not identify a significant ATAL signal. In  
 102 situ mass spectrometry analysis also reveal that the aerosols within the ATAL mainly  
 103 consisted of ammonium nitrate and organics, during a measurement campaign in  
 104 2017 (Appel et al., 2022).
- 105 3. Increased anthropogenic emissions in Asia already started in the early 1960s (not  
 106 the late 1990s) associated with the so-called ‘green revolution’. The green revo-  
 107 lution describes the introduction of high-yielding crop varieties and massive us-  
 108 age of fertilizers (nitrates), greatly increasing the food production as detailed in  
 109 Liu et al. (2021) and Pingali (2012). (Smith et al., 2011) show that global SO<sub>2</sub>  
 110 emissions began increasing around 1850 and peaked in the 1970s and slowly de-  
 111 creased towards the late 1990s. SO<sub>2</sub> emissions in China started exponentially in-  
 112 creasing in ~1950. Hence, even if the existence of the ATAL depended on human-  
 113 made emissions, we would expect an ATAL signal long before the late 1990s.

114 Within this study we are exploring the existence of the ATAL for years prior to the late  
 115 1990, based on earliest possible high quality space borne observations and first respec-  
 116 tive model simulations. Is it possible that limitations to the data or incomplete analy-  
 117 sis hide earlier instances of ATAL?

## 118 2 Methods

### 119 2.1 SAGE I

120 The Stratospheric Aerosol and Gas Experiment (SAGE, hereafter referred to as SAGE  
 121 I) was a solar occultation instrument aboard the Applications Explorer Mission-B (AEM-  
 122 B) satellite (Chu & McCormick, 1979; McCormick et al., 1979). It delivered measurement  
 123 profiles from the cloud top (or 0.5 km) up to 40 km altitude of aerosol extinction and  
 124 concentrations of ozone and nitrogen dioxide from February 1979 to November 1981. Here,  
 125 we make use of the aerosol extinction data set version 1, given on two wavelengths: 1000

**Figure 1.** SAGE I (1000 nm) full time series of mean aerosol extinction values between the tropopause and 1 km above the tropopause at different latitude bands. The latitude bands are inspired by the Mt. St. Helens location at  $46^{\circ}\text{N}$ . Significant eruptions by Mt. St. Helens (May 7<sup>th</sup> and June 5<sup>th</sup> 1980) and Pagan (May 15<sup>th</sup> 1981) are indicated with black vertical lines.

126 nm and 450 nm. However, because the 450 nm channel is only scientifically recommended  
 127 for cloud filtering (i.e. to use information provided by the ratio of both channels), we  
 128 do not show averaged profiles from the 450 nm channel (Thomason et al., 1997). SAGE  
 129 I is reported every half kilometer, with a vertical resolution of around 1 km, similar to  
 130 SAGE II (Damadeo et al., 2014). In the early 1980s, SAGE I data were validated through  
 131 a correlative measurement program (P. B. Russell et al., 1984; Kent & McCormick, 1984).  
 132 Together with SAM II it provides the first space-borne aerosol data set, ranging back  
 133 as early as 1979. While the SAM II instrument only covered latitudes  $> 60$  degree, SAGE  
 134 I is the first instrument providing aerosol observations of the Asian monsoon region.  
 135 SAGE I data released its most recent revision in 1986 and thus the current data set lacks  
 136 the improved understanding reflected in later data sets like SAGE II v7.0 (Damadeo et  
 137 al., 2013). Figure 1 shows that timing, location, altitude and magnitude of the aerosol  
 138 extinction values after the Mt. St. Helens eruption (June 1980) and Alaid, Pagan (April  
 139 and May 1981) are reasonable, i.e. the data catch larger values associated with the events,  
 140 and are therefore trustworthy enough for further analysis. Hence, it is the earliest data  
 141 set that can be used for the investigation of the ATAL.

142

## 2.2 SAGE II

143 The Stratospheric Aerosol and Gas Experiment II (SAGE II) ([https://doi.org/10.5067/ERBS/SAGEII/SOLAR\\_BINARY\\_L2-V7.0](https://doi.org/10.5067/ERBS/SAGEII/SOLAR_BINARY_L2-V7.0)) was the follow up instrument to SAGE  
 144 I, mounted on board the Earth Radiation Budget Satellite (ERBS). It produced ozone,  
 145 water vapor, nitrogen dioxide and aerosol extinction observations at four wavelengths  
 146 from 1984 to 2005. Here, we use the aerosol extinction data set version 7.0 at 452 nm,  
 147 525 nm and 1020 nm wavelength. With its solar occultation measurement technique, it  
 148 measured up to 30 profiles per day (15 during sunrise, 15 during sunset), however, dur-  
 149 ing the year 2000 the number of profiles obtained per day decreased to 16. It has a ver-  
 150 tical resolution of about 0.5 to 1 km and a variable horizontal resolution, which depends  
 151 on the angle between the Sun and the direction of motion of the spacecraft (between hun-  
 152 dreds and thousands of  $\text{km}^2$ ) (Damadeo et al., 2014). The data set of SAGE II is still  
 153 extensively used for aerosol extinction observations in the Upper Troposphere and Lower  
 154 Stratosphere (for example in Thomason et al. (2021); J.-P. Vernier, Thomason, Pommereau,  
 155 et al. (2011); Thomason and Vernier (2013)) and has also been used for an ATAL evo-  
 156 lution investigation of V15, using a specifically designed cloud filter (Thomason & Vernier,  
 157

158 2013). Most (75%) of the SAGE II data record was influenced by atmospheric enhanced  
 159 aerosol mixing ratios from two ‘large’ volcanic eruptions (El Chichón in 1982 and Mt.  
 160 Pinatubo 1991) (Thomason et al., 2021) and is therefore excluded from ATAL investi-  
 161 gations. Conservative data quality checks and cloud filtering procedures were conducted  
 162 according to NASA SAGE-team standards. Other space-borne atmospheric aerosol ob-  
 163 servations during a similar time frame as SAGE II exist. Starting from September 1991  
 164 until June 2005 the NASA mission Upper Atmosphere Research Satellite (UARS) per-  
 165 formed measurements of the Earth’s atmosphere, with a special focus on stratospheric  
 166 ozone. The onboard instrument Halogen Occultation Experiment (HALOE) provided  
 167 measurements of aerosol extinction, as well as some trace gas information. During the  
 168 first 4-5 years of measurements the upper atmosphere was loaded with volcanic aerosol  
 169 and it has been found that UTLS aerosol extinction observations by HALOE are not as  
 170 reliable as SAGE II observations (Thomason, 2012). UARS, HALOE observations are  
 171 therefore not included in this study.

## 172 2.3 SAGE III/ISS

173 The Stratospheric Aerosol and Gas Experiment on the International Space Station  
 174 (SAGE III/ISS) is a solar and lunar occultation instrument, providing profile observa-  
 175 tions since June 2017. The sampling, measurement technique and resolution is similar  
 176 to its forerunner SAGE II. For aerosol extinction data, it delivers profile measurements  
 177 of nine wavelengths. Here, we make use of the 521 nm channel version 5.1 for best com-  
 178 parisons with SAGE II observations. The profile observations are available on a 0.5 km  
 179 vertical grid.

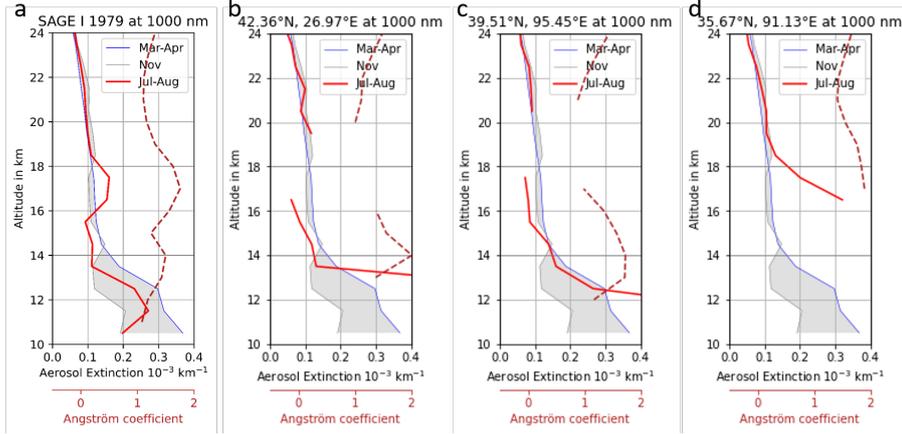

## 180 2.4 CAM5-MAM7

181 For model simulations of the ATAL in 1979 and 1980 in our study the global Com-  
 182 munity Earth System Model (CESM1.2) was used, based on the Community Atmospheric  
 183 Model (CAM5.1) with its full chemical core for both troposphere and stratosphere, cou-  
 184 pled with the Modal Aerosol Model (MAM7), according to Liu et al. (2012). The setup  
 185 of the simulations is described in Bossolasco et al. (2021) for a thorough ATAL trend-  
 186 analysis. The model derives the content of sulfate aerosols, secondary and primary or-  
 187 ganic aerosols, ammonium particles, and dusts. Nitrate aerosols are not simulated in the  
 188 model. Because MERRA-2 meteorological input data are not available for 1979, the model  
 189 is initialized with MERRA instead. However, using MERRA data is not that uncom-  
 190 mon for ATAL studies (see, (e.g. Fairlie et al., 2020)). Cloud signatures have been fil-  
 191 tered out by selecting simulated profiles only below a given extinction threshold (Bossolasco  
 192 et al., 2021).

## 193 3 Results

### 194 3.1 Space-borne ATAL analysis for 1979 (SAGE I)

195 We use earliest possible space borne observations of stratospheric aerosol within  
 196 the AMA for ATAL investigations in 1979. With increased aerosol extinction values af-  
 197 ter the Mt. St. Helens (18/05/1980 at 46°N, 122°W), Ulawun (7/10/1980 at 5°S, 151°E),  
 198 Alaid (27-30/4/1981 at 51°N, 156°E) and Pagan (15/05/1981 at 18°N, 145°E) eruptions  
 199 (e.g. J. Russell, 1981), SAGE-I data for 1980 and 1981 are excluded from further anal-  
 200 ysis (see Figure 1). The year 1979, however, is not impacted by stratospheric aerosol events  
 201 and can therefore be used as the earliest suitable year. We apply a commonly used tech-  
 202 nique by averaging over a defined space- and time frame (we choose: 15-45°N, 15-105°E,  
 203 July and August, a compromise from the choices of Ploeger et al. (2015); Santee et al.  
 204 (2017) and J.-P. Vernier, Thomason, and Kar (2011)), best representative for the over-  
 205 all location and time of the AMA, using the same cloud- and data quality filtering as

**Figure 2.** (a) Averaged profile for SAGE I measurements within  $15\text{-}45^{\circ}\text{N}$ ,  $15\text{-}105^{\circ}\text{E}$  in July and August 1979 in red, March and April in blue and November in grey. The grey area represents ‘background’ conditions (i.e. the area between the blue and grey lines). The Ångström exponent corresponding to the red profile is indicated with the dashed, dark red line. Single profiles averaged for (a) with values at 16.5 km altitude are shown in (b), (c) and (d) in red, with their respective location and Ångström exponent.

206 applied in V15. The respective averaged profile is presented in Figure 2a, compared to  
 207 background conditions. The profile shows a clear aerosol extinction enhancement within  
 208 the AMA at around 17 km altitude. Even the Angstrom exponent, a parameter, which  
 209 gives indications about the optical thickness and size of observed particles, points to a  
 210 distinct layer of smaller sized aerosols in the AMA, with values at around 1.9, similar  
 211 to what was found for SAGE III/ISS ATAL observations for 2017 (Kloss et al., 2019).  
 212 Hence, first impressions suggest that SAGE I observations show the presence of ATAL  
 213 in 1979, however, closer investigations of the individual profiles (Figure 2 b, c and d),  
 214 indicate that the slight aerosol extinction enhancement in Figure 2a only originates from  
 215 a single profile (Figure 2d). Aerosol extinction measurements below 16 km altitude in  
 216 Figure 2d are excluded as a result of the applied cloud filter (i.e. the ratio between the  
 217 extinction channels at 450 to 1000 nm is below 2). Because of the low number and alti-  
 218 tude coverage of averaged profiles, we can neither confirm nor exclude the existence of  
 219 the ATAL with SAGE I observations. However, this result gives motivation to revisit the  
 220 SAGE II data record, to test the significance of increased aerosol extinction observations,  
 221 attributed to the ATAL, as observed in V15.

### 222 3.2 Space-borne ATAL analysis for 1989 to 2004 and 2017 (SAGE II and 223 SAGE III/ISS)

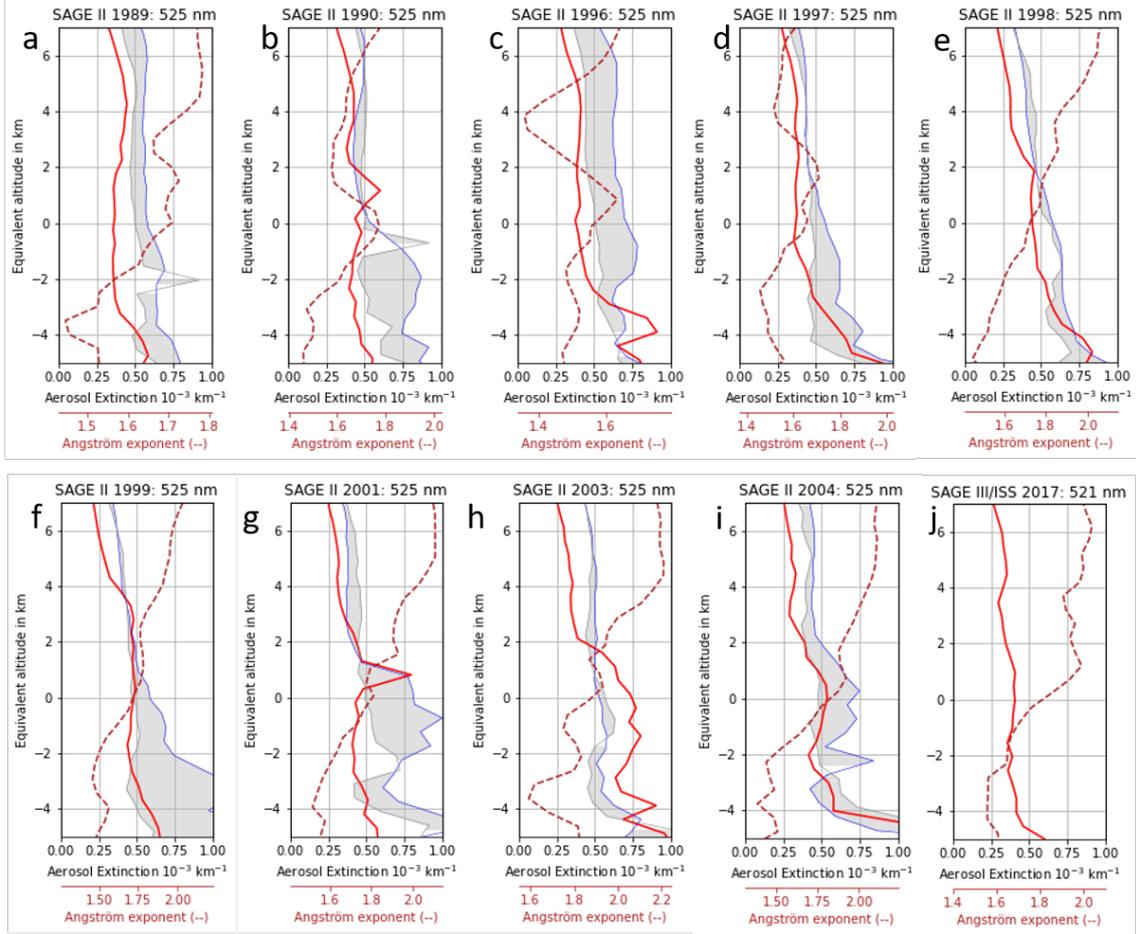

224 We use aerosol optical depth (AOD) information from the Global Space-based Strato-  
 225 spheric Aerosol Climatology (GloSSAC) from Kovilakam et al. (2020) (their Figure 15),  
 226 as well as the complete SAGE II mean aerosol extinction time series at different latitude  
 227 ranges to identify phases of volcanic influence to be excluded for our ATAL analysis. Hence,  
 228 nine years of SAGE II satellite observations remain for ATAL investigations (1989, 1990,  
 229 1996, 1997, 1998, 1999, 2001, 2003 and 2004), presented in Figure 3 a-i. Compared to  
 230 V15 and Thomason and Vernier (2013), we use the current (updated) SAGE II data ver-  
 231 sion 7.0 (compared to version 6.2). We, furthermore add the analysis of the most recent  
 232 suitable year for ATAL investigations with SAGE III/ISS. For the time period 2018 to  
 233 2022, stratospheric aerosol in the Asian monsoon region was permanently enhanced due

234 to several volcanic eruptions (Ambae 2018, Raikoke and Ulawun 2019, Soufriere 2021 and  
 235 Hunga Tonga 2022). Therefore, only the Asian monsoon season in 2017 is suitable for  
 236 ATAL investigations. Because the SAGE III/ISS mission only started in June 2017 and  
 237 Kloss et al. (2019) found significant aerosol enhancements in the AMA region from the  
 238 Canadian wildfires, starting from mid-August 2017, no background profiles are available  
 239 for our SAGE III/ISS analysis (Figure 3j).

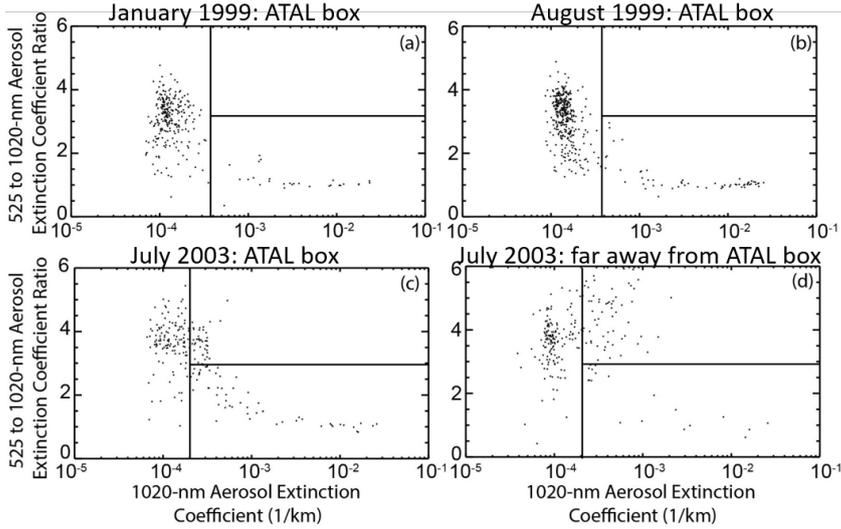

240 For most of the investigated years no significant layer of enhanced aerosol extinction val-  
 241 ues, compared to background conditions is visible. For many of the presented years, how-  
 242 ever, the Angström exponent points to a layer of smaller sized aerosols (higher Angström  
 243 exponent values) at AMA altitudes, for most years (clearly visible in Figure 3 a,b,c,d,i  
 244 and j). The year-to-year SAGE II and SAGE III/ISS ATAL analysis, as presented in Fig-  
 245 ure 3 gives neither clear indications of a significant ATAL signature nor would it be pos-  
 246 sible to derive any kind of quantitative estimation or trend of those averaged observa-  
 247 tions. This unconvincing result, however, gives motivation to study each of the presented  
 248 ATAL seasons separately, to investigate whether a clear ATAL signature can be found  
 249 in individual measurement profiles.

250 Here, we choose to present further investigations for the years 1999 and 2003, for  
 251 which an ATAL signature of enhanced aerosol extinction values at the tropopause alti-  
 252 tude ( $\pm 2$  km) could be interpreted compared to background conditions from Figure  
 253 3. We examine the SAGE II ATAL record for the years 1999 and 2003 by showing the  
 254 525 to 1020 nm aerosol extinction ratio versus 1020 nm aerosol extinction coefficient for  
 255 the respective ATAL altitudes for selected representative periods and spatial extents with  
 256 no additional filtering (e.g. clouds) in Figure 4. The vertical and horizontal lines (90<sup>th</sup>  
 257 percentile of extinction coefficient and median of the 525 to 1020 nm extinction coeffi-  
 258 cient ratio, respectively) divide the analysis space into 3 regions, an unenhanced region  
 259 on the left, and two regions on the right both with enhanced aerosol extinction coeffi-  
 260 cient but divided between higher extinction coefficient ratio and lower extinction coeffi-  
 261 cient ratio. Data points within the lower right box (Figure 4) are generally consistent  
 262 with, and consistently interpreted as, aerosol/cloud mixtures (Thomason & Vernier, 2013).  
 263 Figure 4a shows the resulting distribution for January 1999, a typical month in the ATAL  
 264 region but away from the expected ATAL season. We see a cluster of data points around  
 265 an extinction coefficient of  $10^{-4}$  km<sup>-1</sup> and a ratio of 3. In addition, we see a tail of points  
 266 stretching from the primary aerosol cluster toward ratios of 1 with extinctions exceed-  
 267 ing 0.01 km<sup>-1</sup>. This tail is observed in the troposphere at all latitudes and is interpreted  
 268 as aerosol/cloud mixture. The respective analysis for the peak ATAL month, August (7  
 269 months later) is shown in Figure 4b. Overall, the figure is extremely similar to the ear-  
 270 lier January case except higher number of data points located in the tail suggesting a  
 271 higher frequency occurrence of clouds in August 1999 in the ATAL region than in Jan-  
 272 uary 1999. Overall, 1999 is typical of most years in the SAGE II record away from those  
 273 strongly affected by the 1991 Mt. Pinatubo eruption. Realistically, we cannot exclude  
 274 the possibility that some of these ‘cloud-aerosol mixture’ observations are in reality low  
 275 ratio/high extinction ATAL enhancements. The fact that all of these enhanced aerosol  
 276 extinction data points are completely consistent with observations outside of the expected  
 277 Asian monsoon time frame, highlights the difficulty of identifying ATAL observations  
 278 in SAGE-like observations. Unlike the behavior shown in 1999, data for July 2003 (Fig-  
 279 ure 4c) show some aerosol in the high extinction coefficient/high extinction coefficient  
 280 ratio area, beyond the typical primary aerosol cluster and the aerosol-cloud mixture tail.  
 281 This suggests the presence of recently nucleated small particles within the ATAL region.  
 282 However, in this case (2003), these somewhat ‘unique data points’ are observed far out-  
 283 side the ATAL region: Figure 4d shows the same analysis as Figure 4c except for a box  
 284 defined by 40-140°W and 20-40°N, (i.e. on the other side of the world). This aerosol is  
 285 also observed in both regions as early as March 2003 and thus it is almost certainly not  
 286 associated with ATAL processes.

287 In general, when we observe rare enhancements of aerosol residing the high extinction/high  
 288 ratio area of the analyses in the ATAL region and timeframe, they can also be observed

**Figure 3.** (a)-(i) SAGE II and (j) SAGE III/ISS aerosol extinction (at 525 nm and 521 nm, respectively) profiles averaged over 15-45 °N, 15-105 °E for March/April (blue), November/December (grey) and July/August (Asian monsoon peak time, red) of each year. Equivalent altitude in km are indicated corresponding to the respective tropopause altitudes of the averaged profiles. The grey area represents the span between the blue and gray profiles. (j) The respective profile for 2017 with SAGE III/ISS. For the red curves 36 (a), 28 (b), 56 (c), 55 (d), 53 (e), 44 (f), 35 (g), 19 (h), 14 (i) and 55 (j) profiles with measurement points at 17 km altitude (ATAL altitudes) were averaged. The Ångström exponent of the red curve is indicated with the dark red, dashed line. (j) No background observations are available in 2017 and the time frame is limited to August 15<sup>th</sup>, because of the arriving aerosol plume from the Canadian fires mid-August in the Asian monsoon region, in the UTLS.

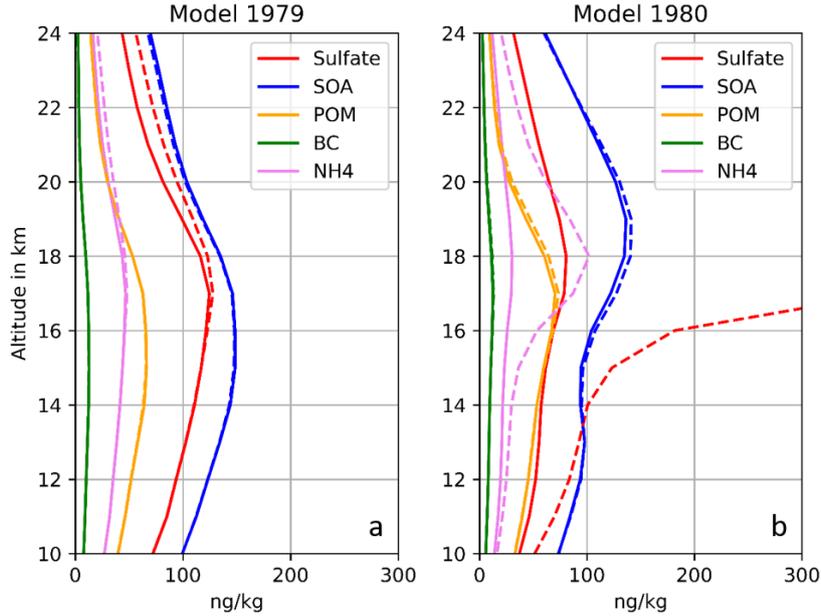

**Figure 4.** SAGE II 525 to 1020 nm aerosol extinction ratio versus 1020 nm aerosol extinction coefficient between the tropopause minus 3 km and 18 km for (a) January 1999 40-140°E, 20-40°N, (b) July 1999, 40-140°E, 20-40°N, (c) July 2003, 40-140°E, 20-40°N and (d) July 2003, 40-140°W, 20-40°N. No additional cloud filter is applied. Vertical lines represent the 90<sup>th</sup> percentile of extinction coefficient and vertical lines are located at the median 525 to 1020-nm extinction coefficient ratio.

289 outside of this window and thus, it is impossible to confidently associate these observa-  
 290 tions with ATAL processes. At the end, we do not feel that it is possible to identify any  
 291 specific SAGE II observations as being associated with ATAL related processes with any  
 292 confidence.

293 The most recent Asian monsoon time frame, which is not influenced by either extreme  
 294 fire events or stratospheric volcanic eruptions was in 2017. In July of 2017 aircraft and  
 295 balloon-based field campaigns (under the EU-project StratoClim and BATAL) took place  
 296 within the AMA with observations identifying a clear ATAL (Mahnke et al., 2021; J.-  
 297 P. Vernier et al., 2018). Figure 3j shows no significant aerosol extinction enhancement  
 298 during the ATAL season in 2017. However, when only averaging mid-August profiles,  
 299 selected according to the occurring transport barrier at that time (PV criteria, accord-  
 300 ing to Ploeger et al. (2015)), a clear ATAL signal appears, as presented in Figure 2 within  
 301 Kloss et al. (2019). Hence, even though there is no doubt about the existence of the ATAL  
 302 during the Asian monsoon season in 2017, the averaged profile of SAGE III/ISS obser-  
 303 vations with commonly used criteria does not find a clear ATAL structure.

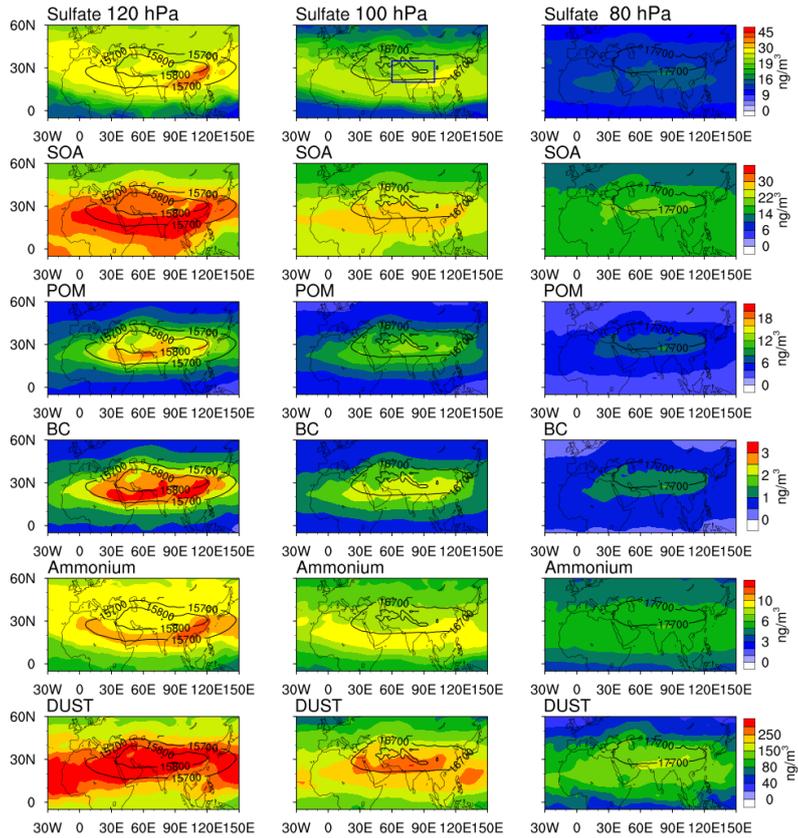

### 304 3.3 Simulation-based ATAL analysis for 1979 and 1980 (CAM5-MAM7)

305 We perform model simulations with the CAM5-MAM7 model as done by Bossolasco  
 306 et al. (2021). Bossolasco et al. (2021) present a detailed trend analysis of the ATAL, in-  
 307 cluding its spatial distribution and composition. Here, we investigate the ATAL for the  
 308 complementary years 1979 and 1980. Vertical profiles of the CAM5-MAM7 simulation  
 309 of aerosol-types-specific concentrations in the ATAL region are shown in Figure 5. A clear  
 310 ATAL structure is apparent with enhanced mass concentration values at around 16 km  
 311 altitude in August 1979, with mineral dust (with values up to 250 ng/m<sup>3</sup> at 120 hPa as  
 312 shown in Figure 6), SOA (secondary organic aerosol) and sulfate (> 100 ng/kg) as dom-  
 313 inant ATAL particles. Note that nitrate aerosols are not accounted for in this model. Sim-  
 314 ulations with and without volcanic emissions (solid vs. dashed lines) exhibit very sim-

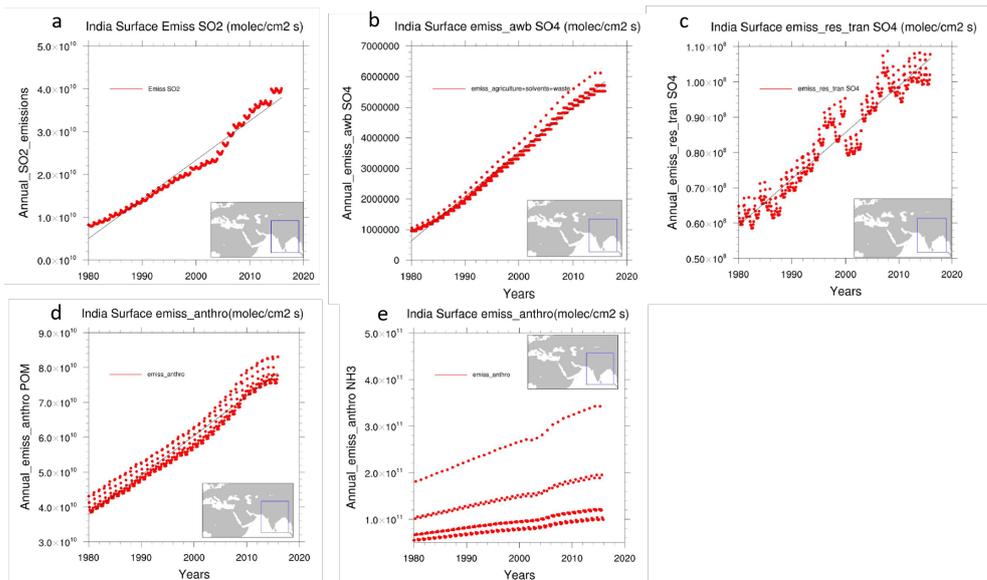

**Figure 5.** (a) Averaged mass concentration from CAM5-MAM7 model simulations, for August 1979 20-35°N, 60-100°E, with aerosol-type-specific information: sulfate particles (red), SOA (blue), POM (yellow), BC (green) and Ammonium (magenta). Dust is not shown. The dashed lines represent simulations where volcanic influence is taken into account. (b) Same as (a) for the year 1980. The respective horizontal distribution is shown in Figure 6 for 1979.

315 ilar values in the aerosol concentrations at these altitudes and in this area. This suggests  
 316 that the ATAL 1979 was not significantly influenced by volcanic eruptions. A model sim-  
 317 ulation for 1980 was conducted and shows an ATAL signal with a similar magnitude as  
 318 observed in Figure 5a. Simulations taking volcanic emissions (i.e. from Mount Saint He-  
 319 lens eruption) into consideration show very different sulfate and NH<sub>4</sub> aerosols vertical  
 320 shapes, with substantially increased concentrations. This is a result of the formation of  
 321 secondary sulfate and ammonium-sulfate aerosols initiated by volcanic SO<sub>2</sub> emissions.  
 322 In Figure 6 we show the horizontal distribution of our ATAL simulations for 1979. This  
 323 reveals a typical horizontal ATAL structure for the different types of aerosols in the model,  
 324 with maxima mass concentration values within the AMA boundaries. Simulations suggest  
 325 that mass concentration values for sulfates, POM (Primary Organic Aerosol), BC  
 326 (Black Carbon) and ammonium have approximately doubled in the 2010s with respect  
 327 to 1979 and 1980 (compared to the modeled ATAL of 2000-2015 from Bossolasco et al.  
 328 (2021)). The increasing ATAL signature with time can be explained by enhancing pol-  
 329 lution and anthropogenic emissions in and around Asia during the past decades. Sur-  
 330 face emissions of human-made SO<sub>2</sub>, SO<sub>4</sub> (from agriculture, solvents, waste and residen-  
 331 tial, transportation), POM and NH<sub>3</sub> steadily increase between 1980 and 2015, accord-  
 332 ing to MERRA-2 data. For SO<sub>2</sub> and NH<sub>3</sub>, we find increases of 40-100%. The correspond-  
 333 ing trends in anthropogenic emissions between 1980 and 2015 for India are shown in Fig-  
 334 ure 7. Main source regions responsible for the ATAL and its composition have been found  
 335 to be located in India, including North India and South of the Tibetan Plateau (e.g. Tissier  
 336 & Legras, 2016; Legras & Bucci, 2020; Clemens et al., 2023). Simulated mineral dust com-  
 337 ponents, which are not directly influenced by human activities, do not show an increas-  
 338 ing trend from 1979 to the 2010 decade. Dust is largely the dominant aerosol type, by  
 339 mass concentration, in our ATAL simulations (up to a factor 10 larger than sulfate aerosols).  
 340

**Figure 6.** Graphical distribution of aerosol mass concentration, from model simulations, averaged for July/August 1979 for the 5 aerosol components presented in Figure 5a and mineral dust, at 120 (left column), 100 (center column) and 80 hPa (right column) pressure levels. Geopotential levels are indicated by black lines. The blue box in the second panel represents the averaging area used for Figure 5b.

**Figure 7.** MERRA-2 trend analysis for human made emissions from India (box  $0-40^{\circ}\text{N}$ ,  $65-95^{\circ}\text{E}$ ) 1980-2015 for (a)  $\text{SO}_2$ , (b)  $\text{SO}_4$  agriculture+solvents+waste, (c)  $\text{SO}_4$  residential+transportation, (d) Primary Organic Aerosol POM and (e)  $\text{NH}_3$ .

#### 4 Discussion

While model simulations (and in situ observations in 2017) point to the existence of a weak, but significant ATAL signal, the SAGE I, II and III/ISS data records show no statistically significant ATAL structure compared to observations outside the AMA, when averaging over the Asian monsoon time frame. The ability to confidently identify ATAL related aerosol using limb data such as SAGE is limited by a number of factors:

- There are relatively few observation opportunities in the ATAL spatial region that, particularly for solar occultation, only occur episodically through the ATAL seasonal life span.
- The high number of clouds that occur in the ATAL region, particularly during the ATAL season due to systematic convective outflow, can result in the loss of observations in the core of this region where the largest and most easily identified aerosol enhancements may occur. As a result, the inference of the presence of enhanced aerosol is dependent on how robustly aerosol can be distinguished from the cloud/aerosol mixtures that are characteristic of SAGE observations globally. Ultimately, this would be straightforward if the ATAL aerosol is primarily the result of the nucleation of new small aerosol from aerosol precursors in a way that mimics small to moderate volcanic activity that increase (or maintain) the 525 to 1020 nm aerosol coefficient extinction ratio (Thomason et al., 2021). Conversely, if the aerosol precursors primarily condense on existing aerosol or existing aerosol is transported from the lower troposphere primarily as relatively large aerosol as the ATAL enhancement, then the optical properties of these aerosol can effectively mimic cloud/aerosol mixture in which enhancements in extinction coefficient are tied with decreases in aerosol extinction coefficient ratio. In this case, separating between what is a ‘cloud’ and what is ATAL would be extremely difficult.
- Furthermore, groups of consecutive SAGE III profile observations within the AMA box appear usually within a time frame of a few days and within a few degrees

of longitude. In other words, most of the averaged profiles within one ATAL season mostly originate from a short time frame (within days) at similar latitudes. The ATAL is a patchy feature and depends strongly on the AMA dynamics each season, which is also demonstrated by the contrasting compositions of the ATAL during different measurements campaigns. Hence, we do not expect that the sampling of a solar occultation instrument is sufficient to give a representative average of the ATAL during the whole AMA season.

- Generally, an increase of the ATAL signal with time is expected, because of increasing anthropogenic emissions in Asia (Fadnavis et al., 2013; Neely et al., 2014; Bossolasco et al., 2021). Therefore, a weaker extinction enhancement in the early 1990s and before is expected and confirmed with the CAM5-MAM7 simulations (Figure 5 and 6). A lower ATAL signal in (potentially) individual profiles makes it even more unlikely to show an ATAL structure for earlier years within the SAGE record.
- Space LiDAR observations or limb observations with significantly higher sampling such as CALIOP and OMPS, are expected to be better suitable for potential ATAL evolution studies. However, their respective time series is not long enough for ATAL investigations in and before the 1990s.

## 5 Conclusions

Space-borne solar occultation observations within the Asian monsoon region are not suitable for the representation of quantitative averaged values, for a highly variable ATAL in space and time during each season. Averages over a given geographical box (both in and out of the ATAL) may drown the ATAL signal while apparent on some individual profiles. SAGE (I, II and III/ISS) aerosol extinction observations (past and present) can therefore neither be used for any kind of trend analysis, nor to exclude the existence of the ATAL for specific years, as it was done in previous studies (e.g. V15, Thomason and Vernier (2013)). The same is expected for quantitative, trend analysis of trace gases within the AMA, using solar occultation observations (e.g. from the Atmospheric Chemistry Experiment Fourier Transform Spectrometer, ACE-FTS).

Averaged SAGE I and II observations for the years 1979 to 2005 can neither confirm nor deny the presence of an ATAL signal and it is impossible to point the first existence of the ATAL to a specific time frame and specific location/region, based on available space-borne observations. On the contrary, individual profiles, with applied cloud filter, within the transport barrier of the AMA, can potentially point to an ATAL signal. However, we find that such features are also observed far outside the ATAL boundaries and season and therefore not highly reliable.

While space-borne observations cannot be used for early investigations of the existence and trend of the annually appearing ATAL, we are left to rely on model simulations. CAM5-MAM7 simulations show a clear ATAL signal for both tested years (1979 and 1980), consisting of both natural appearing aerosols (e.g. dust) and from human-made emissions (e.g. sulfates, organics, ammonium). A detailed simulation-based ATAL evolution analysis starting from pre industrial years to the early 2000s is planned as a follow-up study.

## Open Research Section
