15 *Revised: December 22, 2021*

16

17 *Key Points*

18 • Approximately 20% of the ocean floor topography has been surveyed by ships, the

19   remaining 80% is predicted by satellite altimetry.

20 • We increased the resolution of the predicted depth using spectral properties of

21   abyssal hills and the characteristic shapes of seamounts.

22 • We estimate the height and radius of 19,723 uncharted seamounts.

23

24

25   *Abstract*

26   To date, approximately 20% of the ocean floor has been surveyed by ships at a spatial

27   resolution of 400 m or better. The remaining 80% has depth predicted from satellite

28   altimeter-derived gravity measurements at a relatively low resolution. There are many

29   remote ocean areas in the southern hemisphere that will not be completely mapped at

30   400 m resolution during this decade. This study is focused on the development of

31   synthetic bathymetry to fill the gaps. There are two types of seafloor features that are

32   not typically well resolved by satellite gravity; abyssal hills and small seamounts (< 2.5

33   km tall). We generate synthetic realizations of abyssal hills by combining the measured

34   statistical properties of mapped abyssal hills with regional geology including fossil

35   spreading rate/orientation, rms height from satellite gravity, and sediment thickness.

36   With recent improvements in accuracy and resolution, It is now possible to detect all

37   seamounts taller than about 800 m in satellite-derived gravity and their location can be

38   determined to an accuracy of better than 1 km. However, the width of the gravity

39   anomaly is much greater than the actual width of the seamount so the seamount

40   predicted from gravity will underestimate the true seamount height and overestimate

41   its base dimension. In this study we use the amplitude of the vertical gravity gradient

42   (VGG) to estimate the mass of the seamount and then use their characteristic shape,

43   based on well surveyed seamounts, to replace the smooth predicted seamount with a

44   seamount having a more realistic shape.

45

46   *Plain Language Summary*

47   The floor of the deep ocean remains as the last uncharted frontier in the inner solar

48   system. The deep seawater (> 1000 m) prevent any type of exploration from

49   conventional satellite remote sensing. Echosounders aboard large vessels have mapped

50   about 20% of the seafloor, however, vast areas in the southern hemisphere will not be

51   mapped in our lifetimes. The deep ocean floor has more than 90% of the active

52   volcanoes; hydrothermal circulation of seawater through the crust of the seafloor

53   spreading ridges replenishes the nutrients needed for life on Earth. This study is an

54   effort to fill the large gaps in seafloor coverage by creating a synthetic abyssal hill fabric

55   using geological information such as the age of the seafloor, the spreading rate and

56   direction when it formed, and the thickness of the sediments covering the original

57   topography. In addition, we use the latest satellite-derived gravity to estimate the

58   locations and shapes of about 20,000 uncharted seamounts. The combination of

59   mapped (20%) and synthetic (80%) topography is useful for modeling ocean circulation

60   and ocean tides although it may give a false impression that 100% of the seafloor has

61   been mapped.

62

63   *Introduction*

64   Bathymetry is foundational data, providing basic infrastructure for scientific, economic,

65   educational, military, and political work. High resolution, deep ocean bathymetry is

66   critical for: (1) understanding the geologic processes responsible for creating ocean floor

67   features unexplained by simple plate tectonics, such as abyssal hills, seamounts,

68   microplates, propagating rifts, and intraplate deformation; (2) determining the effects of

69   bathymetry and seafloor roughness on ocean circulation, ocean mixing, and climate; and

70   (3) understanding how marine life is influenced by seafloor depth, roughness, and

71   interactions of currents with the seafloor [*Yesson et al.,* 2011]. The Seabed 2030 project

72   [https://seabed2030.org] "aims to bring together all available bathymetric data to

73   produce the definitive map of the world ocean floor by 2030 and make it available to

74   all."   The Seabed 2030 global compilation will be based on swath mapping using

75   multibeam sonar which has a spatial resolution of about 400 m at a typical ocean depth

76   of 4 km [*Mayer et al.,* 2018].

77

78   The Seabed 2030 project has made considerable progress over the past few years by

79   increasing the multibeam coverage in public compilations from 11% [e.g., GEBCO 2019;

80   Tozer et al., 2019] to more than 20% today [GEBCO 2021]. Much of this data has been

81   made available by the international community with nearly complete coverage of

82   several exclusive economic zones as well as dense coverage of areas of high scientific

83   interest. The remaining 80% of the seafloor has depth predicted from a combination of

84   spatially dense satellite altimeter gravity measurements and sparse soundings to

85   provide the large-scale shape of the ocean basins as well as to calibrate the local ratio of

86 bathymetry-to-gravity [e.g., *Smith and Sandwell,* 1994]. The spatial resolution of these

87 predicted depths is limited to approximately the mean ocean depth because of the

88 upward continuation smoothing effects from Newton's law of gravity. The best satellite

89 gravity models available today can only resolve ½ wavelength of 6 km when the regional

90 depth is 4 km [*Tozer et al.*, 2019]. Thus, the resolution of gravity-predicted depth is

91 more than 10 times worse than the Seabed 2030 objective.

92

93 There are many remote ocean areas in the southern hemisphere that will probably not

94 be completely mapped at 400 m resolution during this decade and well beyond (e.g.,

95 Figure 1).   This study is focused on the development of **SYN**thetic **BATH**ymetry

96 **(SYNBATH)** to fill the gaps. The synthetic bathymetry has the geostatistical properties of

97 real seafloor bathymetry but it is not as accurate as ship soundings. While the synthetic

98 data will be replaced with real soundings as they become available in the future, in the

99 interim such realistic realizations can provide key inputs for a number of important

100 scientific applications. We will discuss such applications, where this synthetic

101 bathymetry is appropriate and valuable, and also discuss uses of synthetic bathymetry

102 that could prove problematic and result in a false impression that Seabed 2030

103 objectives have been achieved.
104

105

106

107   Figure 1. Available ship soundings including single-beam data (thin lines) and multi-beam data (thick lines)

108   in a remote region of the South Pacific based on the GEBCO 2021 bathymetry [*Weatherall et al.,* 2020]

109   grid superimposed on a map of North America for scale. There are many areas on this map that are more

110   than 100 km from a depth sounding. Moreover, removal of the lower resolution single beam soundings

111   would dramatically reduce the spatial coverage leaving many gaps greater than 400 km.

112

113   There are two types of seafloor features that are not well resolved by satellite gravity;

114   abyssal hills and small seamounts (< 2.5 km tall). As described more completely in the

115   next section, one can generate synthetic abyssal hills by combining the measured

116   statistical properties of mapped abyssal hills with regional geology including fossil

117   spreading rate/orientation, rms height from satellite gravity, and sediment thickness

118   [*Goff and Arbic*, 2010; *Goff*, 2010; *Goff*, 2020]. At scales greater than about 6 km ½

119   wavelength, the location or "phase" of the synthetic hills matches the actual location

120   based on gravity predicted depth. At shorter scales, the synthetic hills have the correct

121   power spectral roll-off and orientation but have random locations completely

122   uncorrelated with the actual abyssal hills. For studies in physical oceanography, creating

123   hills with the correct height, spectral slope and orientation is more important than hills

124   having the correct location or phase [*Scott et al.,* 2011; *Timko et al.*, 2017] although

125   phase information will be needed for fully resolved models.

126

127   The second type of unresolved seafloor feature are seamounts less than about 2.5 km

128   tall [*Menard,* 1964; *Staudigel et al.,* 2010; *Kim and Wessel,* 2011; 2015]. Because of

129   significant improvements in the accuracy and resolution of the satellite gravity since the

130   *Kim and Wessel* [2011] study, it is now possible to detect seamounts taller than about

131   800 m [*Gevorgian et al.,* 2021] and their location can be determined to an accuracy of

132   better than 1 km. However, the width of the gravity bump is much greater than the

133   actual width of the seamount. Therefore, the seamount predicted from gravity will

134   underestimate the seamount height and overestimate its base dimension. This results in

135   a seamount flank slope that may be 10 times smaller than the actual slope [*Becker and*

136   *Sandwell*, 2008]. As in the case of abyssal hills, the magnitude of the slope of the

137   seamount influences the paths of currents as well as the generation of eddies and

138   internal waves. The studies by *Smith* [1988] and *Gevorgian et al.,* [2021] have used

139   depth soundings to characterize the shapes of smaller seamounts. In this study we use

140   the amplitude of the vertical gravity gradient (VGG) to estimate the mass of the

141   seamount and then use their characteristic shape to replace the smooth predicted

142   seamount with a Gaussian seamount having a more realistic shape.

143

144   *Modeling Abyssal Hills*

145   We use the model of *Goff and Jordan* [1988; 1989] to generate synthetic abyssal hills;

146   the power spectrum of the topography has the following functional form

147

148

$$P\left(k_x,k_y\right)=\frac{\pi h_{rms}^2}{v k_n k_s}\left[\frac{k_h^2}{k_s^2}\cos^2\left(\theta-\theta_s\right)+\frac{k_h^2}{k_n^2}\sin^2\left(\theta-\theta_s\right)\right]^{-(v+1)}$$

149   (1)

150

151   where $\left(k_x,k_y\right)$ is the 2-D wavenumber, $k_h=\left(k_x^2+k_y^2\right)^{1/2}$ is the magnitude of the 2-D

152   wavenumber, h_{rms} is the rms of the abyssal hill height, $\left(k_s,k_n\right)$ are the characteristic

153   wavenumbers for the abyssal hills in the strike and normal directions, respectively, θ_s is

154   the azimuth of the strike of the abyssal hills and v is the Hurst number (~0.9) that

155   determines the rate of spectral roll-off. The five parameters $\left(h_{rms},k_s,k_n,\theta_s,v\right)$ vary

156   geographically depending on the geological setting at the time of the formation of the

157   abyssal hills [*Goff*, 2020]. In addition, as the plate ages, sediments can partially or fully

158   cover the hills which reduces their visible height.

159

160   The rms height h_{rms} of the hills is taken from the most recent analysis [*Goff*, 2020] of the

161   altimeter-derived gravity anomaly [*Sandwell et al.,* 2019]. RMS height was reduced in

162   sediment covered areas by a factor of 0.1 times the sediment thickness [*Straume et al.,*

163   2019]. The characteristic wavenumbers $\left(k_s,k_n\right)$ and Hurst number v were taken from

164   the analysis of *Goff* [2010] and the orientation of the abyssal hills θ_s is from the recent

165   global age compilation of *Seton et al.* [2020].

166

167   To replace the predicted bathymetry with more realistic abyssal fabric, we first prepare

168   the 5 global parameter grids (+/- 74 degrees latitude) to have consistent spatial

169   coverage. This was done by extending the grids of $\left(k_s, k_n, \theta_s, \nu \right)$ and then tapering the

170   rms height grid h_{rms} to go smoothly to zero on its perimeter. As in previous studies [e.g.,

171   *Goff and Arbic*, 2010], we populate a 30 arcsecond global grid with uniform random cell

172   values. A 2-D spatial filter is calculated from the inverse transform of the spectral model

173   in equation 1 at each cell location and convolved with the random grid; a new filter is

174   computed at each grid cell to accommodate the spatial variations in the 5 parameters.

175   This operation is equivalent to inverse Fourier transformation of the product of the

176   amplitude spectrum with a random phase spectrum. However, though computationally

177   far more efficient, this alternative does not allow for the imposition of the statistical

178   heterogeneity that is critical for our purposes. The resulting synthetic bathymetry (e.g.,

179   Figure 2) is added to a previous iteration of global depth to make a new synthetic

180   bathymetry data set. We then perturb the global predicted bathymetry model to exactly

181   match these synthetic data using a standard remove/grid/restore approach [e.g.,

182   *Sjöberg,* 2005]. A spline in tension gridder is used [*Smith and Wessel,* 1990]. This

183   becomes an updated predicted depth that is used in a second remove/grid/restore using

184   the real sounding data. The final result exactly matches the real soundings where they

185   exist and blends smoothly into the updated predicted depth in the data voids. The fully

186   sedimented areas and areas with no abyssal hill predictions have depth based entirely

187   on sparse soundings and the gravity prediction.

Figure 2. Example of synthetic abyssal hills around the Indian Ocean Triple Junction illustrate their variation with spreading direction and rate.

Mapping Seamounts

Although multibeam sonar is best suited for mapping smaller seamounts, satellite altimetry can be used to find larger seamounts (> 700 m) through disturbances in Earth's gravity field. These perturbations are due to the difference in density between basalt and seawater. There are four main errors and uncertainties that arise from satellite altimetry: upward continuation, measurement noise, seafloor roughness, and sediment cover [*Wessel et al.*, 2010]. The first global seamount maps (8556 seamounts) were created from widely-spaced Seasat altimeter profiles [*Craig and Sandwell*, 1988]. Since the Seasat mission there have been a number of altimeter missions that have greatly improved the accuracy and coverage of the gravity field [Wessel, 2001, 14639 seamounts]. This has enabled the construction of the vertical gravity gradient (VGG) which is a spatial derivative of the gravity field [e.g., *Wessel,* 1997]. This spatial derivative amplifies short wavelengths and suppresses long wavelengths so it is a valuable tool for locating smaller features on the ocean floor [*Kim and Wessel,* 2011; 2015]. However, the spatial derivative also amplifies short wavelength noise which limits seamount detectability. The recently released VGG has significantly lower noise levels

209   because of new altimeter data from CryoSat-2, SARAL/AltiKa, Jason-1/2 and the

210   Sentinel-3a/b missions [*Sandwell et al.,* 2014; 2019]. After comparing the old and new

211   VGG, it was found that the signal to noise ratio has increased by at least a factor of 2,

212   indicating that multiple altimetry sources can improve gravity data and help find

213   unmapped features on the ocean floor.

214

215   *Gevorgian et al.,* [2021] have used the latest version of the VGG model [*Sandwell et al.,*

216   2019] to update the global seamount catalog of *Kim and Wessel* [2011; 2015]. The

217   original KW catalog had 24643 seamount identifications. The new analysis was

218   performed in 4 steps using the display and digitization features in Google Earth: 1) The

219   VGG was displayed as a grey-scale image with black-to-white saturation set at -53 to +38

220   Eotvos units. 2) Known tectonic features [*Matthews et al.,* 2011] were plotted as lines.

221   3) The KW15 catalog was also plotted as points. 4) *Gevorgian et al.,* [2021] visually

222   identified circular anomalies in the VGG in the deep ocean (> ~500 m) away from known

223   and well-mapped tectonic features. The lower noise level in the latest VGG grid enabled

224   the identification of circular anomalies as small as 5 Eotvos which is about ½ the

225   threshold of the KW15 analysis. *Gevorgian et al.,* [2021] found 10796 previously

226   unidentified seamounts and also determined that 513 seamounts in the KW15 catalog

227   were mis-identifications. The revised KW catalog has 24129 seamounts so the total

228   seamount count is 34925. Figure 3 shows a region on the eastern flank of the East

229   Pacific Rise where there is complete multibeam coverage. The VGG image shows

230   numerous circular anomalies associated with small seamounts. We use these to

231   develop a method of estimating seamount height and radius from the VGG anomaly.
232

233

Figure 3. (a) Bathymetry on the eastern side of the East Pacific Rise (EPR) where three seamounts have been mapped by multibeam sonar. The two labeled KW are from the Kim and Wessel [2011] catalog while the seamount labelled New-08049 is from *Gevorgian et al.,* [2021]. (b) VGG in the same area showing three seamounts that are relatively circular.

Modeling Seamounts

Previous studies have found that small seamounts are typically circular in planform and have a fixed height to base ratio largely independent of height [*Smith and Jordan,* 1988; *Wessel,* 2001]. *Smith* [1988] studied bathymetry profiles across 85 seamounts and found they could be fit by a flattened cone having a height to base radius ratio of ~0.21 and a flattening of 0.15. More recently, *Gevorgian et al.,* [2021] studied 739 seamounts having

247   at least 50% coverage of the seamount and complete coverage of the summit area.

248   Using these well-surveyed seamounts they found, on average, they are best fit by a

249   Gaussian function

250

251    $$h(r) = h_o e^{\frac{-r^2}{2\sigma^2}}$$ (2)

252

253   where h_o is the seamount height, r is the radius from the center of the seamount, and

254   σ is the characteristic width of the seamount. Their analysis found a high correlation

255   between seamount radius and slope such that that $\sigma = 2.4 h_o$. This corresponds to a

256   maximum seamount slope of 0.25 independent of seamount height. Here we use this

257   model, along with the observed VGG, to estimate the shape of each seamount. There

258   are several parameters that go into this gravity modeling including mean ocean depth

259   surrounding the seamount d_o, seamount density relative to seawater $\Delta\rho$, crustal

260   thickness, elastic thickness, mantle density, and seamount height h_o. We show next

261   that for seamounts < ~2 km in height, the VGG is insensitive to the elastic thickness so

262   we can assume the seamounts are uncompensated. In this case the mean crustal

263   thickness and mantle density are not needed.

264

265   This insensitivity to elastic thickness is easily verified using the *grdseamount* and *gravfft*

266   modules in Generic Mapping Tools (GMT) [*Wessel et al.,* 2019]. A typical seamount,

267   shown in Figure 4, has a height of 1500 m, a $\sigma = 2.4 h_o$, a density of 2700 kg m^{-3}, and a

268   base depth of 4000 m. To assess the effects of elastic thickness, we computed the VGG,

269   including 3 nonlinear terms in the *Parker* [1973] expansion. For an elastic thickness T_e of

270   2 km as well as 100 km (uncompensated), the two VGG models have almost equal

271   signatures so we can assume small seamounts are uncompensated as in [*Watts et al.*
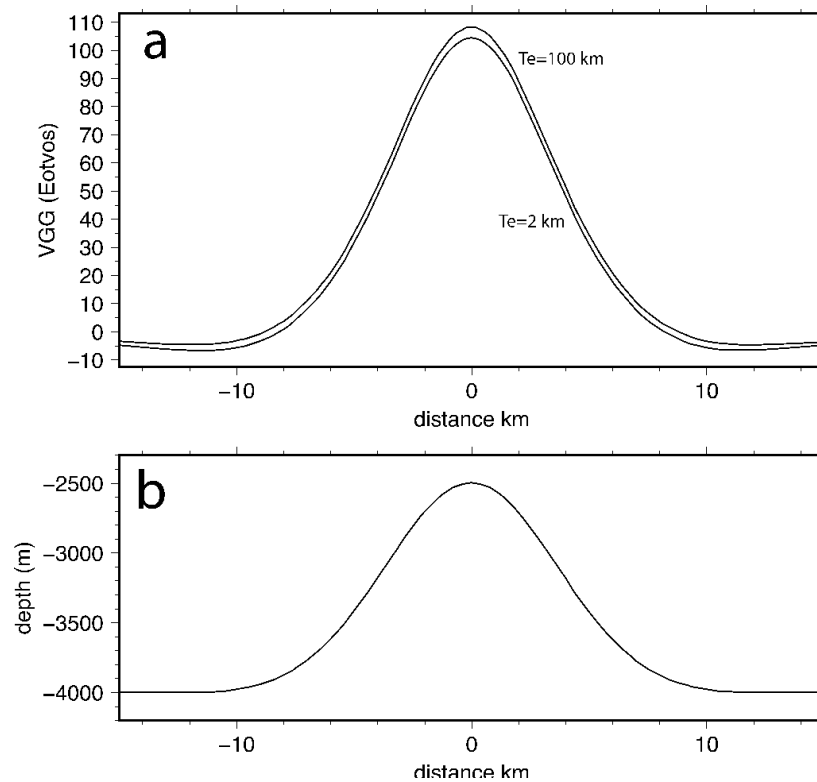

272   2006].

273

274

275

276 Figure 4. Vertical gravity gradient (VGG - a) computed from a Gaussian seamount (b) that is 1500 m tall,

277 has a $\sigma = 2.4h_o$. The two VGG curves, which are very similar, correspond to well compensated

278 topography (T_e = 2 km) and uncompensated topography (T_e = 100 km).

279

280 Based on this calculation the remaining free parameters are seamount height, seamount

281 density, and base depth. The base depth is calculated from the median depth in a 90 km

282 by 90 km area surrounding the seamount to be modelled.

283

284 To further test the validity of this simple model for a small seamount we analyzed

285 topography and VGG for three seamounts in an area of the southern East Pacific Rise

286 where there is complete multibeam coverage (Figure 3). Two of the seamounts are

287 from the *Kim and Wessel* [2011] compilation while the third is recently identified in the

288 VGG [*Gevorgian et al.,* 2021]. The basic characteristics of the seamounts are provided in

289 Table 1.

290

291 Table 1. Characteristics of modeled seamounts

label	lon	lat	base depth(m)	seamount height (m)	gravity (mGal)	VGG (Eotvos)
KW-13664	-110.90	-18.23	3461.5	2140	53.4	143.7
KW-13666	-110.84	-17.54	3409.5	1343.5	18.5	50.8
New-08049	-112.23	-18.71	3255.5	1209.5	12.9	44.7

292

293   Using these well surveyed seamounts, we can perform forward modeling to establish

294   the density that provides the best fit. From the observed topography we calculate the

295   VGG and compare with the observations. An additional low-pass filter, with a

296   wavelength of 16 km, was applied to the model VGG to match the low-pass filtering that

297   was used to construct the VGG data [*Sandwell et al.,* 2019]. Table 2 shows the median

298   absolute deviation (L1-norm) as a function of seamount/crustal density for each of the

299   three seamounts. We find that the misfit is not very sensitive to the density. A much

300   more extensive study by *Watts et al.* [2006] using 9752 seamounts shows the best

301   density is 2800 kg m^{-3}. This value is consistent with our results from modeling just three

302   small seamounts.

303

304   Table 2. Misfit (L1-norm) versus seamount density in Eotvos

	2650 kg m^{-3}	2700	2750	2800	2850	2900	no model
KW-13664	4.51	4.34	4.33	4.43	4.50	4.56	10.49
KW-13666	4.35	4.28	4.19	4.19	4.20	4.21	8.74
New-08049	4.49	4.51	4.53	4.54	4.54	4.45	5.51

305

306   An example of the fit of the model to the largest of the three seamounts is shown in

307   Figure 5. The model based on topography with a density of 2800 kg m^{-3} provides an

308   excellent fit to the VGG data. As a final check we generated VGG models using a

309   Gaussian approximation to the actual seamount topography for large and small

310   seamounts in the region. These results, shown in Figures 5 and 6, demonstrate that the

311   VGG from a Gaussian seamount is a good match to the VGG from the actual seamount

312   topography. The important parameter is the seamount height. Because most

313   seamounts are uncharted we will use this approach, with a Gaussian shaped seamount,

314   to generate synthetic seamounts in unmapped areas.

315

316   Figure 5. (a) Bathymetry of the largest of the three seamounts, KW-13664 (200 m contours). (b, f)

317   Measured VGG for seamount (5 Eotvos contours). (c) Model VGG using a density of 2800 kg m^{-3}. (d)

318   Difference between observed VGG and model VGG (L1-norm, 4.43 Eotvos, 5 Etovos contours). (e) Model

319   bathymetry using a Gaussian seamount (200 m contours). (g) Model VGG for Gaussian model bathymetry.

320   (h) Difference between observed VGG and Gaussian model VGG (L1 7.04 Eotvos, 5 Etovos contours).

321

322   Figure 6. (a) Bathymetry of the smallest of the three seamounts, New-08049 (200 m contours). (b+f)

323   Measured VGG for seamount (5 Etovos contours). (c) Model VGG using a density of 2800 kg m^{-3}. (d)

324   Difference between observed VGG and model VGG (L1 4.54 Eotvos, 5 Etovos contours). (e) Model

325   bathymetry using a Gaussian seamount. (g) Model VGG for Gaussian bathymetry (200 m contours). (h)

326   Difference between observed VGG and conical model VGG (L1 5.13 Eotvos, 5 Etovos contours).

327

328   Based on this analysis, we estimated heights for 34925 seamounts in the updated

329   catalog basically using the method of *Wessel,* [2001]. This was done by extracting a 90

330   km by 90 km grid of VGG and SRTM15 (V2.3) depth data centered on each seamount.

331   The base depth was computed from the median depth of this larger 90km grid and a

332   Gaussian seamount (equation 2) was superimposed on this base depth using $\sigma = 2.4 h_o$

333   a density of 2800 kg m^{-3}. The VGG model, generated using *gravfft* in GMT, was low-pass

334   Gaussian filtered at 16 km wavelength to match the low-pass filter applied to the VGG

335   data. Finally the L1 norm difference between the model and data VGG was computed

336   for a smaller 33 by 33 km area centered on the seamount. This modeling was repeated

337   for seamount heights ranging from 700 to 2600 m in steps of 100 m. The model with the

338   lowest misfit was selected as the height. A histogram of the number of seamounts

339   versus their estimated height is shown in Figure 7 (top). A histogram of seamounts

340   versus the L1 norm of the misfit is shown in Figure 7 (bottom). For all seamounts, the

341   number increases with decreasing seamount height until 1300 m when the number

342   decreases at smaller heights. Our results show that the KW analysis, using noisier VGG

343   data, captured most seamounts taller than about 1500 m. The new analysis found many

344   more seamounts with heights between 1100 and 1500 m. Most of the VGG models have

345   misfits between 5 and ~20 Eotvos. The new seamounts are generally smaller and have

346   lower L1-misfit. For the remainder of this study we exclude all seamounts with heights

347   greater than 2500 m and less than 800 m since they are at the ends of the histogram.

348   We also reduce the height of any seamount having a depth shallower than -100 m to

349   force the model summit depth of -100 m. In other words we don't want to create any

350   false islands or atolls although these cases may be interesting places to survey with

351   multibeam. This results in 31602 modeled seamounts.

352

353   We investigate how many of these seamounts are constrained by depth soundings by

354   using the SRTM15 V2.3 source identification grid (SID) to locate all the seamounts

355   having at least one sounding within 3 km of the center of the seamount. This resulted in

356   11879 seamounts that are at least partly constrained by a real depth sounding and

357   19723 seamounts that are completely uncharted.
358

359

360   Figure 7 (top) Histogram of the seamount height based on our analysis of all seamounts (red), KW

361   seamounts (green), and new seamounts (blue). (bottom) Histogram L1 misfit of model VGG to each

362   seamount.

363

364   *Results*

365   Prior to filling the gaps with synthetic bathymetry, we assembled new sounding data not

366   available for the *Tozer et al.,* [2019] study. The latest V2.3 of the SRTM15+ grid includes

367   905 new multibeam sonar cruises that are archived at the National Center for

368   Environmental Information [https://www.ngdc.noaa.gov/mgg/bathymetry/multibeam.html].

369   These were processed with MB-System [*Caress and Chayes*, 2008] to remove outer

370   beams and flatten the rails of the innermost beams, and subsequently used to update

371   the 15-arcsecond grid. We performed 3 iterations of visual editing of bad soundings

372   (~700 edits) to prepare the grid as the base layer for the GEBCO 2022 global grid. In

373   addition we obtained 9 large composite grids from IFREMER that greatly improved the

374   bathymetry coverage of the Gulf of Aden [*Hebert et al.,* 2001], the Lesser Antilles

375   volcanic arc [*Talbot and Loubrieu,* 2020], French Guiana margin [*Loubrieu,* 2019], the

376   Rodrigues triple junction [*Mendel et al.,* 2000], the Kerguelen plateau [*Loubrieu,* 2019],

377   Reunion island [*Sisvath et al.,* 2011], Saint-Paul and Amsterdam Islands [*Loubrieu et al.,*

378   2020], the Southwest Indian ridge [*Sauter and Mendel,* 2000], and the North Fiji basin

379   [*Ruellan,* 2001].

380

381   Gaps in the SRTM15+ grid were filled with synthetic bathymetry to create SYNthetic

382   BATHymetry (SYNBATH V1.2). An example of the enhancement related to just abyssal

383   hills is shown in Figure 8. The upper plot shows the standard SRTM15+ grid with the

384   combination of single- and multibeam bathymetry and smooth gravity-predicted depths

385   filling the gaps. The Indian Ocean triple junction at 70˚ longitude and -25.7˚ latitude is

386   the intersection of the Central Indian ridge (CIR) to the north, the Southeast Indian ridge

387   (SEIR), and the Southwest Indian ridge (SWIR). The flanks of each ridge have ridge-

388   parallel abyssal hills as seen in the available multibeam bathymetry. The slower

389   spreading SWIR has left a V-shaped scar on the seafloor where there is a nearly 90˚

390   degree change in the orientation of the abyssal hills reflecting the change in age

391   gradient [e.g., *Seton et al.*, 2020]. The center plot shows the SYNBATH bathymetry which

392   is identical to the SRTM15+ bathymetry where there are real ship soundings and has

393   synthetic abyssal hills in the gaps. The boundaries between the actual and synthetic

394   bathymetry are difficult to observe. One would expect a sharp change in the "phase" of

395   the abyssal hills across these boundaries. However, a part of the synthetic abyssal fabric

396   contains a correct-phase pattern that is derived from the gravity prediction. Figure 8c

397   shows the difference between the SYNBATH and SRTM15+ bathymetry grids. The

398   difference is zero at grid cells constrained by ship data and matches the synthetic

399   abyssal hills (Figure 2) in the gaps.

400

Figure 8. Bathymetry of Indian Ocean Triple Junction. (a) Based on multi- and single-beam soundings and gravity-predicted bathymetry to fill the gaps. (b) Based on multi- and single-beam soundings and synthetic abyssal hills superimposed on gravity-predicted bathymetry to fill the gaps. (c) Difference shows that the two methods are identical where measured soundings are available and have synthetic abyssal hills in other areas.

407

408   An example of the enhancement primarily related to small seamounts is shown in Figure

409   9 for a poorly charted region just south of the Galapagos spreading ridge. The smaller

410   predicted seamounts, having no bathymetry soundings, are short and wide (Figure 9a).

411   The sharpened seamounts are tall and narrow following the shape of the Gaussian

412   model $\sigma = 2.4h_o$ (Figure 9b). The difference between these two models (Figure 9c)

413   shows the combined effects of added abyssal fabric and sharpened seamounts. In areas

414   where there are actual multibeam depth soundings, the two models agree.

415

416   Since there are many steps in constructing this SYNBATH bathymetry at 15 arcseconds

417   we provide a brief overview. There is a common *polishing* technique used each time a

418   new data layer is added so we first describe that remove/grid/restore approach as

419   follows: 1) assemble some new data (e.g. real soundings or synthetic hills or seamounts;

420   2) remove the previous model from each new data point; 3) identify spatial gaps (> 20

421   km from a new data point) and add zero-valued data points at these locations; 4) use

422   the GMT *surface* module with a tension of 0.6 and a convergence limit of 1 m and up to

423   200 iterations; 5) add the previous model so the result exactly fits the new data. Given

424   this common *polishing* approach the overall construction method is:

425

426   1) Use the gravity prediction method described in *Smith and Sandwell* [1994] and

427   updated in *Tozer et el.,* [2019] to make a global 1-minute bathymetry.

428   2) Polish that bathymetry using actual soundings.

429   3) Use the 1-minute base depth to generate synthetic abyssal hill data and

430   synthetic seamount data. So the model from step 2) provides the base depth for

431   both the hills and seamounts. Also note the synthetic seamount data extend

432   only 1.5 σ from the seamount center. This promotes better blending of the

433   synthetic seamounts into the regional bathymetry while retaining the data

434   having maximum slope which occur at 1.0 σ .

435   4) Create a 15-arcsecond grid following the methods in *Tozer et al.,* [2019].
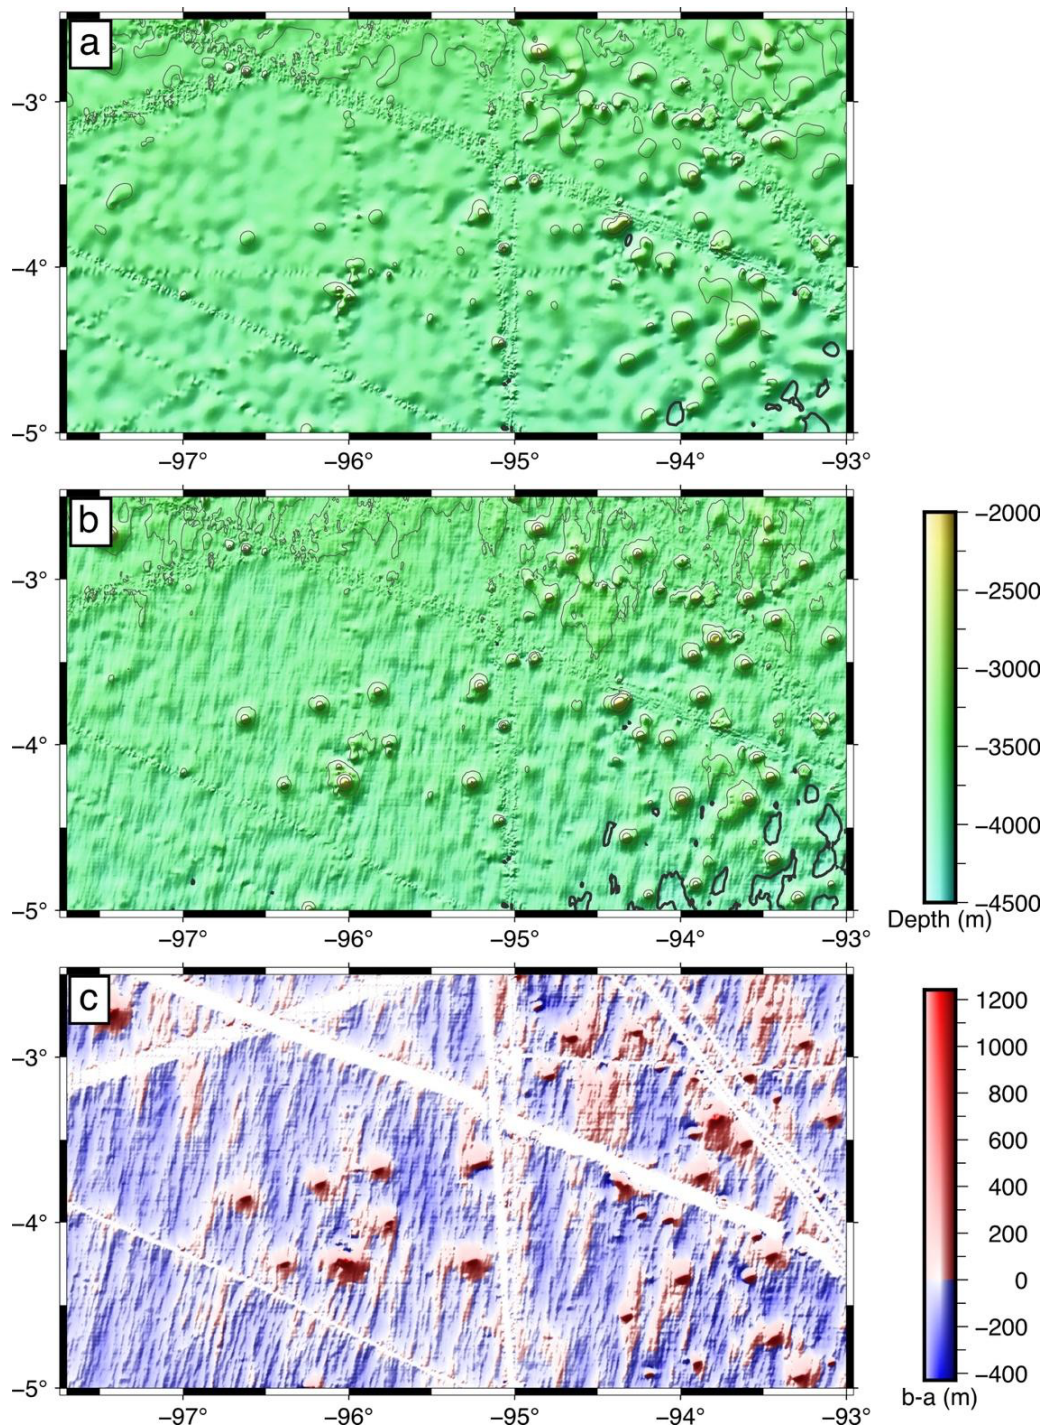

436   5) Polish the step 4) grid with synthetic abyssal hills.

437   6) Polish the step 5) grid with synthetic seamounts.

438   7) Polish the step 6) grid with all the real soundings.

439   8) Combine the land topography data with the grid from 7).

440

441   This is a rather complex recipe. However, it is designed to inherit the long-wavelength

442   shape of the ocean basins from original depth soundings. The satellite-derived gravity is

443   used next to update the bathymetry in the 160-16 km wavelength band. Short

444   wavelengths between 16 and 1 km are updated with synthetic abyssal hills. This is

445   followed by an update using the Gaussian seamounts which, as in the real world,

446   overprint the abyssal hills. Finally, the grid is polished using real depth soundings.

447

448

449

450

Figure 9. Bathymetry of an area south of the Galapagos spreading ridge. (a) Based on multi- and single-beam soundings and gravity-predicted bathymetry to fill the gaps. (b) Based on multi- and single-beam soundings, synthetic abyssal hills and sharpened seamounts superimposed on gravity-predicted bathymetry to fill the gaps. (c) Difference shows that the two methods are identical where measured soundings are available and have synthetic abyssal hills in other areas.
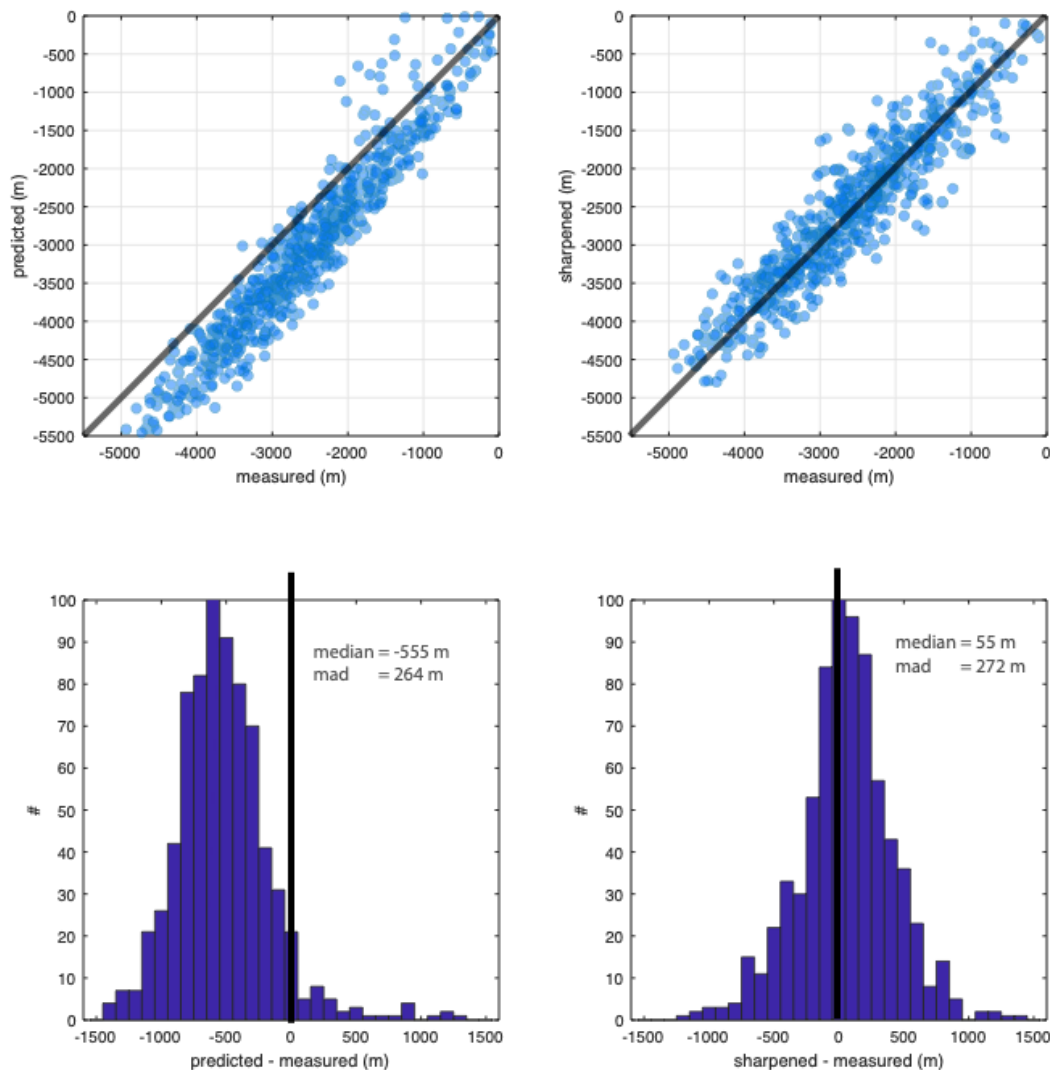

456

457

458

459   *Uncertainty of the Synthetic Bathymetry*

460   Two approaches were used to assess the accuracy of the synthetic bathymetry with

461   respect to the gravity-predicted depths. First we compared the accuracy of seamount

462   summit depths for the 739 well surveyed seamounts from the *Gevorgian et al.,* [2021]

463   study. When constructing the global predicted depths we first construct a global

464   bathymetry grid using only the satellite-derived gravity as described in the *Tozer et al.,*

465   [2019] study. Available depth soundings are used to calibrate the topography-to-gravity

466   ratio in the 160-18 km wavelength band averaged over an area about 320 km in

467   diameter. The predicted bathymetry in areas of complete multibeam coverage has the

468   same characteristics as the bathymetry in the gaps so the actual multibeam soundings

469   can be used to assess the accuracy of the predicted depth. Figure 10 (left) shows a

470   comparison of the predicted and measured summit depth of the 739 well-surveyed

471   seamounts. As discussed above, the predicted summit depths are almost always less

472   than the actual depth. This analysis shows that the median difference is -555 m and the

473   median absolute deviation (MAD) is 264 m. The same analysis for the sharpened

474   seamounts based on VGG modeling (Figure 10 right) has a much smaller median

475   difference of 55 m and a slightly larger median absolute deviation of 272 m. This

476   analysis shows that the sharpened seamounts have more accurate summit depths

477   although the Gaussian shape model does not recover the details of the actual seamount

478   shape.

479

Figure 10. (left) Gravity-predicted summit depth versus measured summit depth. The predicted summit depth is commonly 555 m deeper than the measured summit depth for these 739 well-charted seamounts. (right) Summit depth for sharpened seamounts versus measured summit depth has a 10 times smaller median difference of 55 m although the uncertainty is slightly larger (272 m).

For the second analysis we have obtained a recent multibeam sonar survey in the North Atlantic collected from the RV Maria S. Merian (GEOMAR, Devey et al., 2020; Wölfl et al., 2020). We selected a subset of these data in a region where there were no previous soundings (Figure 11b) and compared the measured depth with both the gravity-predicted depth (Figure 11a) and the predicted depth augmented with synthetic abyssal hill fabric (Figure 11c). As expected the gravity-predicted depth is much smoother than the actual depth with a median difference of -66 m and a median absolute deviation

493   (MAD) of 241 m. The synthetic bathymetry has abyssal hills that look similar to the

494   measured abyssal hills but the random location of the synthetic hills does not match the

495   actual measured location resulting in a median depth difference of 8 m and a MAD of

496   323 m. Therefore the addition of the synthetic abyssal hills has increased the error in

497   the depth by a factor of 1.34. This highlights that the synthetic bathymetry should not

498   be used for any application where knowing the depth of specific points is important but,

499   as discussed above, the synthetic bathymetry has small scale roughness and slope

500   characteristics that better match the actual bathymetry.
501

502

503   Figure 11. (a) Predicted depth based on gravity in the 160-18 km wavelength band is very smooth. (b)

504   Measured seafloor depth from GEOMAR cruises. (c) Synthetic depth where the gravity-predicted depth

505   has been augmented with synthetic abyssal hills as well as sharpened seamounts.

506

507   *Uses of Synthetic bathymetry*

508   This synthetic bathymetry has some appropriate uses as well as some uses that are

509   inappropriate (Table 3) so it will be important to educate the users on how to use the

510   product. A significant danger is that the general public could examine the synthetic

511   bathymetry using a graphical tool such as Google Earth and conclude that the seafloor

512   has been completely mapped at ~500 m resolution. Therefore, there must be an

513   additional graphical layer, or style, to indicate what is real and what is synthetic.

514

515   The applications where this product is **not useful** are mainly aligned with GEBCO

516   applications. These include seafloor geography and feature names. All of these synthetic

517   features lie at base depths greater than ~1000 m so they are irrelevant for any kind of

518   navigation except the 149 seamounts extending to within 200 m of the sea surface;

519   these need to be flagged with red dots and eventually surveyed [

520   https://www.star.nesdis.noaa.gov/star/documents/meetings/extReview/presentations/

521   5CommTrans/CT2_WSmith.ppt]. This product is not useful for establishing the

522   boundaries of the outer continental shelves for the law of the sea. The product is not

523   useful for any kind of detailed deployment of seafloor instrumentation although it can

524   provide a regional sense of seafloor roughness at scales larger than 1 km. Since the

525   synthetic bathymetry is confined to the deep ocean where sediments are thin it is not

526   useful for any applications on the continental margins.

527

528   There are three applications where this product is **marginally useful**. (1) In terms of

529   education and outreach it could provide misinformation that we are done mapping the

530   deep oceans. However, like the early hand-drawn bathymetric maps from *Heezen and*

531   *Tharp* [1959] and GEBCO [*Hall,* 2006], the realistic synthetic bathymetry could inspire

532   students to better understand marine geology and plate tectonics. (2) The product could

533   help with establishing a range of possible tsunami propagation models based on

534   statistical realizations of abyssal fabric and seamounts [*Sepulveda et al.,* 2020]. (3) It

535   could be useful for understanding habitats over unmapped, moderately large

536   seamounts.

537

538 The synthetic bathymetry is **most useful** for studies where a realistic seafloor roughness

539 is needed. This includes models of ocean circulation [*Adcroft et al.,* 2004; *Chassignet et*

540 *al.,* 2007] and internal wave generation, dissipation, and mixing driven by tidal and other

541 low-frequency flows over the rough bottom [*Goff and Arbic*, 2010; *Polzin et al.,* 1997;

542 *Gille et al.,* 2000; *Jayne and St. Laurent,* 2001; *Egbert and Ray*, 2003]. In addition, rough

543 seafloor affects the propagation of acoustic waves [e.g., *Mckenzie,* 1961; *Chin-Bing et*

544 *al.*,1994]. The product could be useful for plate tectonic studies since one can see where

545 the abyssal hill fabric disagrees with nearby multibeam mapping which will provide data

546 on how to revise tectonic models. Finally, the product could be useful for planning

547 shipboard surveys of seamounts and volcanic ridges as well as a tool for planning the

548 optimal ship path for mapping rough seafloor.

554

555 *Conclusions and Future Improvements*

556

557 Our major conclusions are:

558 ● Bathymetry predicted from satellite altimeter-derived gravity cannot resolve the

559   small-scale fabric of the deep ocean associated with abyssal hills and seamounts.

560   There are many remote areas that will not be mapped by ship in this decade.

561 ● We extend two methods to fill these gaps with higher resolution synthetic

562   bathymetry using information on the tectonics, geology, and sediment distribution in

563   the deep oceans.

564 ● Synthetic abyssal hills are generated using an anisotropic statistical model based on

565   high resolution multibeam surveys in a variety of tectonic settings. The orientation of

566   the hills uses the latest seafloor age maps.

567 ● Small seamounts > 700 m tall can be accurately located in satellite-altimeter derived

568   gravity but their shape cannot be resolved. We use ~800 well-surveyed small

569   seamounts to calibrate the expected shapes of and create synthetic bathymetry for

570   all seamounts in the 800-2500 m height range.

571 ● These two synthetic data sets are used to add a small-scale bathymetry component

572   (1-16 km) to the global predicted depth. This provides a new starting model for a

573   remove/grid/restore re-gridding of available single and multibeam ship soundings.

574 ● We generate two global bathymetry/topography products at 15 arcseconds using

575   identical ship soundings. The SRTM15+ product has gaps filled with smooth predicted

576   bathymetry and serves as the base layer for the 15 arcsecond GEBCO grid.   The

577   SYNBATH product has gaps filled with synthetic bathymetry from abyssal hills and

578   seamounts superimposed on the smooth predicted bathymetry.

579 ● The SRTM15+ product is suitable for applications in seafloor geography, law of the

580   sea, seafloor instrumentation and cables and highlighting the need to fill the gaps

581   before 2030.

582 ● The SYNBATH product is suitable for any application where an accurate seafloor

583   roughness is needed such as modeling ocean currents and tidal friction and the

584   generation and dissipation of internal waves.

585

586 In the future we plan to continue to improve the resolution of gravity-predicted depth

587 as well as to work with GEBCO to assemble more multibeam sounding data. With these

588 efforts we can roll-back the spectral and spatial contributions of the synthetic

589 bathymetry. Ka-band altimeters such as SARAL/AltiKa and SWOT promise a dramatic

590 improvement in marine gravity/bathymetry accuracy and resolution.

591

599

600 *Open research and data availability* - The global bathymetry grids and the

601 characteristics of the 35,000 seamounts, and Google Earth overlays are all available at

602 the ZENODO repository, https://zenodo.org/deposit/5784502, DOI

603 10.5281/zenodo.5784502, in addition we keep a copy at our own open web site

604 https://topex.ucsd.edu/pub/ . The VGG grids and overlays are in the global_grav_1min

605 folder, the synthetic bathymetry and products are in the synbath folder, and the

606 SRTM15+ bathymetry and products are in the srtm15_plus folder. Figures and most

607 calculations were performed using GMT (https://www.generic-mapping-tools.org) and

608 MATLAB (https://www.mathworks.com/products/matlab.html). We also have all

609 archived versions of our global grids in one location

610 https://topex.ucsd.edu/pub/archive/ .
