Key Points:

- First observations of extreme vertical velocities in the polar summer mesosphere.
- The observed solitary wave in a varicose mode resembles a mesospheric bore, with large vertical extent and vertical velocities.
- Such extreme events might have been missed or ignored in previous observations of vertical velocities or other mesospheric observations.

Corresponding author: Jorge L. Chau, chau@iap-kborn.de

Abstract

The polar summer mesosphere is the Earth's coldest region, allowing the formation of mesospheric ice clouds. These ice clouds produce strong polar mesospheric summer echoes (PMSE) that are used as tracers of mesospheric dynamics. Here we report the first observations of extreme vertical drafts ($\pm 50 \text{ ms}^{-1}$) in the mesosphere obtained from PMSE, characterized by velocities more than five standard deviations larger than the observed vertical wind variability. Using aperture synthesis radar imaging, the observed PMSE morphology resembles a solitary wave in a varicose mode, narrow along propagation (3–4 km) and elongated ($> 10 \text{ km}$) transverse to propagation direction, with a relatively large vertical extent ($\sim 13 \text{ km}$). These spatial features are similar to previously observed mesospheric bores, but we observe only one crest with much larger vertical extent and higher vertical velocities.

Plain Language Summary

Extreme events are ubiquitous of geophysical flows. Example of these events are tornadoes and Rogue waves in the lower atmosphere and oceans, respectively. In the mesosphere, the boundary of Earth's atmosphere and outer space, extreme events could also occur, although this region is poorly observed. Here we present the first observations of vertical velocities more than five times their expected standard deviation. These observations are possible by tracking and imaging strong mesospheric radar echoes that occur in the summer at polar latitudes, with a radar used in a radio camera mode. The morphology of our observations resembles previously observed instabilities called bores or wave walls, but with much larger vertical velocities and vertical extents.

1 Introduction

Extreme events are ubiquitous to geophysical flows, e.g., tornadoes or rogue waves (e.g., Tippett & Cohen, 2016; Adcock & Taylor, 2014). In the mesosphere (60–90 km), extreme events could also exist. This region is difficult to observe since it is too high for meteorological balloons, and too low for satellites to fly in and make in-situ measurements. Therefore, observations of extreme events and their respective impacts in this region are not easy to identify and study. Nonetheless, this atmospheric region hosts a number of interesting optical and radio phenomena like noctilucent clouds (NLC) and polar mesospheric summer echoes (PMSE) (e.g., Thomas & Olivero, 1986; Ecklund & Balsley, 1981; Hoppe et al., 1988).

During summer months at mid and high latitudes, the mesosphere is the coldest place on Earth with temperatures as low as 130 K due to dynamical processes that drive the atmosphere away from radiatively controlled state (e.g., Lübken et al., 1999). One of the most challenging, important, and intriguing mesospheric measurements are vertical winds. Vertical winds are usually smaller than horizontal winds, but they have significant effects on the atmospheric dynamics, composition, and electrodynamics (e.g., Larsen & Meriwether, 2012). Their mean synoptic-scale values are expected to be in the order of centimeters per second and are difficult to measure directly (e.g., Gudadze et al., 2019). On the other hand measurements made with ground-based radars, passive optics, lidars, as well as in-situ chemical traces, show high values varying by up to $\pm 10 \text{ ms}^{-1}$ (e.g., Hoppe & Fritts, 1995; Gardner & Liu, 2007; Lehmacher et al., 2011). Similar and even higher values have been observed at higher altitudes in the thermosphere (e.g., Larsen & Meriwether, 2012). These high values can occur with the same sign for minutes to hours.

Although part of this variability is attributed to Kelvin-Helmholtz, mesospheric bores and other instabilities (e.g., Chau et al., 2020), the drivers for the majority of observations of large and/or persistent values are not obvious. Waves propagating through the region appear to be connected to the vertical wind variability; either they come from below or are generated locally via instabilities, nonlinear interaction with other waves or turbulence (e.g., Gardner et al., 1995; Fritts et al., 2004; Larsen & Meriwether, 2012). Moreover, high variability in vertical winds have been reproduced in direct numerical simulations (DNS) in flows similar to those in the mesosphere (Marino et al., 2015), including extreme values under some special flow conditions (Feraco et al., 2018). Understand-

ing and characterizing the vertical wind variability of the mesosphere and higher altitudes (thermosphere) are important for explaining their effects on dynamics, composition, chemistry, and electrodynamics of these regions (e.g., Larsen & Meriwether, 2012).

In this work, we focus on extreme vertical drafts observed in the polar summer mesosphere. These observations have been made with the Middle Atmosphere Alomar Radar System (MAARSY) located in northern Norway (69.30°N, 16.04°E). Observations of PMSE have been routinely made with MAARSY since 2010 (Latteck et al., 2012). After more than 20 years of active research, the physics behind PMSE is well understood. Their signal strength depends on electron density, turbulence, and charged-ice particles (e.g., Rapp & Lübken, 2004) and they are good tracers of atmospheric winds (e.g., Sato et al., 2017).

Based on two summers of continuous observations and many years of experience, the event we present is extreme since our measured vertical velocities reach values as high as more than five times their standard deviation (σ_w). We start describing the observing modes. Our radar results are presented in Section 3, followed by a discussion and possible connections to previously observed mesospheric instabilities.

2 Radar observing modes

MAARSY is an active phased array that consists of 433 three-element cross-polarized Yagi antennas and operates at 53.5 MHz. Its main beam one-way half-power beam-width is 4°. On reception, either all 433 elements, or up to 7 groups of 49 elements, or up to 15 out of 55 groups of 7 elements can be used (e.g., Latteck et al., 2012, for more details).

PMSE are routinely observed with MAARSY using two quasi-simultaneous main modes: (a) multi-beam, and (b) radar imaging (e.g., Gudadze et al., 2019; Urco et al., 2019). These modes have been used during the summers of 2016 and 2017, except for a few days where other modes were used to support special requests. Both modes run with 1 ms interpulse period. Since horizontal winds are expected to be within $\pm 150 \text{ ms}^{-1}$, the multi-beam mode has been configured to allow a Nyquist velocity of $\pm 35 \text{ ms}^{-1}$. On the other hand the radar imaging mode allows a Nyquist velocity of $\pm 175 \text{ ms}^{-1}$, suitable to study other echoes, e.g., non-specular meteor echoes (Chau et al., 2014).

Given the velocity aliasing in the multi-beam mode, in this work we use only data from the radar imaging mode, which observes for 30 s every 180 s. This mode uses only one vertically pointing transmitting beam using all 433 elements, while 16 antenna groups

103 are used on reception, 15 of them for radar imaging. A spectral moment method has been
 104 implemented to obtain: signal, mean radial velocity and spectral width. Radial veloc-
 105 ities from slightly off-vertical locations could have contributions from horizontal veloc-
 106 ities. However, unrealistic supersonic horizontal winds (more than 1500 ms^{-1}) would be
 107 required to generate the large ($\sim 50 \text{ ms}^{-1}$) observed velocities.

108 Radar imaging has been obtained by applying the Maximum Entropy method on
 109 the cross-spectra data from combinations of receiving antenna pairs (e.g., Hysell & Chau,
 110 2006; Urco et al., 2019). Since the selected 15 receiving antennas do not have the same
 111 beam width, the imaging inversion has been performed only within $\pm 8^\circ$ zenith angles.
 112 This angular coverage also allows for the observation of PMSE outside the main illumi-
 113 nated area, if strong echoes are present there.

114 Besides the PMSE observations, in this work we also used the horizontal wind ob-
 115 servations with a specular meteor radar (SMR) located also in Andoya (e.g., Chau et al.,
 116 2017). This system consists of one single element Yagi antenna on transmission and five
 117 single element antennas on reception arranged in an interferometer configuration. On
 118 reception echoes from meteor trails perpendicular to the line of sight are detected and
 119 identified. The radial velocity and location (range and angle) of each meteor trail within
 120 selected altitude and temporal bins are used to estimate a mean horizontal wind vector
 121 for that bin (e.g., Hocking et al., 2001). Such vector components are obtained assum-
 122 ing a homogeneous wind inside the illuminated area, i.e., a circle of approximately 400
 123 km diameter at 86 km altitude.

124 **3 Results**

125 The extreme event of vertical drafts that occur on July 16, 2016 is shown in Fig-
 126 ures 1a to 1c. Figure 1a shows the signal-to-noise ratio (SNR) as a function of altitude
 127 and time. The vertical velocities and spectral widths are shown in Figures 1b and 1c,
 128 respectively.

129 The event in question occurred between 04:25 and 05:00 universal time (UT) and
 130 is characterized by: (a) episodes of large vertical updrafts and downdrafts lasting a few
 131 minutes at around 86 km, (b) large spectral widths, and (c) echoes appearing to move
 132 up and down according to the measured mean vertical velocities, and (d) their strength
 133 increasing (decreasing) when going up (down). Outside this time interval, the PMSE spec-

134 tral moments behave within expected values, i.e., vertical velocities within $\pm 5 \text{ ms}^{-1}$, spec-
 135 tral widths below 5 ms^{-1} , and echoes occurring in multiple layers.

136 In Figures 1d to 1t normalized spectrograms for selected times around the extreme
 137 event are shown. Each spectrum is obtained from ~ 30 s continuous observations. The
 138 striking features in this figure are the large positive and negative vertical drafts well out-
 139 side $3\sigma_w$, reaching high absolute values (e.g., 65 ms^{-1} at 04:28:21 UT or -45 ms^{-1} at 04:36:03
 140 UT). Except for the spectra at 04:41:11 (1o) and 04:43:46 (1n) UT, the spectra are com-
 141 posed of one or two velocity peaks at a given altitude. Given that the illuminated vol-
 142 ume has a radius of about ~ 5 km in the horizontal direction at these altitudes, the
 143 multi peak features are a result of multiple regions of enhanced backscattering within
 144 the illuminated volume. The presence of multiple peaks gives rise to large values of spec-
 145 tral widths. The red dashed lines indicate the $3\sigma_w$ based on two months of continuous
 146 observations in 2016.

147 From radar imaging, we have obtained spatial information of features within the
 148 illuminated volume. Figures 2a to 2f show selected 2D spatial planes of imaging around
 149 04:30:54 UT. The large scale 30-min averaged horizontal winds obtained from a closely
 150 located specular meteor radar are shown in arrows as a reference. Radar imaging results
 151 clearly indicate that the extreme updrafts and downdrafts are localized in horizontal space,
 152 with 3–4 km width along the x axis, and at least 8–12 km elongation along the y axis,
 153 where x - and y -axis are rotated 50° East of North. An animation of similar frames from
 154 04:00 to 05:30 UT every 150–170 s can be seen in Movie S1. The imaging results are also
 155 used to verify that the inferred vertical velocities are mainly due to vertical wind and
 156 not to a horizontal wind contamination, since areas of large vertical drafts are observed
 157 at or close to overhead inside the vertical transmitting beam. For typical mesospheric
 158 horizontal winds ($\pm 150 \text{ ms}^{-1}$), their contamination in our vertical estimates would be
 159 at most within $\pm 4 \text{ ms}^{-1}$.

160 The temporal evolution of these spatial features is summarized in Figures 2g to 2n
 161 as function of x (i.e., X-Time Doppler-Intensity, XTDI) (left) and y (YTDI) (right) for
 162 selected altitudes. The extreme drafts are elongated along y at all altitudes, and drift
 163 along x . At 89 km, the updraft is observed to cover at least 16–20 km in x , appearing
 164 around 04:20 and disappearing around 04:45 UT. The irregularities causing these echoes
 165 move up from around 86 km and stay at 89 km for at least 25 min. At 81.5 km, down-

166 drafts are also elongated along the y axis and drift generally along x . However, they are
 167 only observed for 2–4 km along x and last less than 5 min. The latter suggests that the
 168 irregularities came down from 86 km or so and disappear after a few minutes. Later the
 169 echoes appear again around 04:55 due to irregularities coming from below and remain
 170 present at least until 05:30 UT. Both regions of updrafts and downdrafts drift at $\sim 11 \text{ ms}^{-1}$
 171 along x , North-East, with respect to an observer on the ground. Note that regions of large
 172 drafts are observed for a longer time in these plots than in the spectra plots in Figure 1,
 173 since the spectra were obtained using all 433 elements on transmission and reception.
 174 The duration, elongation and horizontal extent of the event should be taken as minimum
 175 values, given the relatively small observing volume, when compared to other imaging ob-
 176 servations (e.g., airglow imagers).

177 Figure 3 shows profiles of horizontal wind magnitude and direction as well as their
 178 vertical gradients. These profiles were obtained with the SMR described above, around
 179 the time of the event. A moderate horizontal wind shear ($24 \text{ ms}^{-1}\text{km}^{-1}$), occurs at the
 180 altitude where the extreme updrafts and downdrafts begin, i.e., 86 km. Recall that these
 181 are mean values representing an area of approximately 400 km diameter at 86 km ob-
 182 tained.

183 4 Discussion

184 The main features of the kilometer-scale extreme event presented here can be sum-
 185 marized as follows: (a) vertical drafts close to $5\sigma_w$ occur during a limited time of ~ 30
 186 minutes on July 16, 2016 around 0430 UT; (b) they occur between 80 and 90 km, (c)
 187 updrafts (downdrafts) up to 65 (45) ms^{-1} occur above (below) 86 km, are observed for
 188 long (short) time, and their associated echoes present larger (smaller) SNR than echoes
 189 at 86 km where they begin; (d) it is localized in horizontal space with widths of 3–4 km
 190 in the x axis, and elongated along the y axis; (e) at the center altitude, the vertical gra-
 191 dient of the background horizontal wind is the largest ($24 \text{ ms}^{-1}\text{km}^{-1}$); (f) the PMSE
 192 layer thickness changes from 3 km (before the event) to 13 km (at the central time), (g)
 193 both drafts drift across the observing volume apparently against the mean horizontal wind
 194 at $\sim 11 \text{ ms}^{-1}$, therefore the duration, elongation and horizontal extent of the event should
 195 be taken as minimum values.

196 **4.1 Verification of our observations**

197 Since our reported vertical velocities are not expected and might be controversial,
 198 in this section we summarize briefly some of the actions we have performed to verify the
 199 validity of our vertical velocity estimates. The first obvious check was range aliasing. Our
 200 unambiguous range is 300 km, echoes coming from 380 km might be range aliased, how-
 201 ever, their range, temporal, and spectral features do not correspond to such altitude. For
 202 example, if they were echoes from radar aurora, they would cover a much larger range
 203 (e.g., Chau & St.-Maurice, 2016). Moreover, plasma instabilities have been ruled out since:
 204 (a) the ionosphere was quiet for a few hours around the event, and (b) the altitude is
 205 too low for plasma instabilities to be generated (e.g., St.-Maurice & Chau, 2016). The
 206 former indicates that strong electric fields are not expected, while the latter is supported
 207 by high collision frequencies around 86 km.

208 Horizontal velocity contamination is a usual suspect on vertical velocity studies,
 209 particularly when studying their mean values (e.g., Gudadze et al., 2019). As we men-
 210 tioned above without considering radar imaging, unrealistic huge supersonic horizontal
 211 velocities would be needed to explain the reported vertical velocities. Moreover in the
 212 imaging results, at a given altitude they would be shown with a transition from red to
 213 blue as the scattering center passes the beam center if the vertical velocity is very small.
 214 Figure 2g clearly shows that the upper/lower altitude regions are red/blue as the event
 215 transits the beam. At most we expect the horizontal contamination to be within $\pm 4 \text{ ms}^{-1}$.

216 The vertical velocity profile is not constant at all altitudes at the central time of
 217 the event (i.e., 04:30), instead, it shows a maximum upward value around 89 km, zero
 218 at 86 km, and maximum downward value around 82 km. A simple integration of this ver-
 219 tical profile, supports the observed vertical extension, i.e., a few kilometers in altitude
 220 in a few minutes.

221 **4.2 Connection to mesospheric bores**

222 A sketch based on the observations is shown in Figure 4. The SNR, vertical veloc-
 223 ity, and spectral width from Figure 1 are combined into an altitude-time-Doppler inten-
 224 sity plot (e.g., Chau et al., 2020), with superimposed arrows indicating w directions, and
 225 expected regions of horizontal wind convergence (C) and divergence (D) (see below). Clearly,
 226 our observed event resembles a solitary wave oscillating in varicose mode, i.e., where the

227 upper part is rising, the lower part is falling, and viceversa. This varicose mode is ex-
 228 pected in internal bores (e.g., Dewan & Picard, 2001) and has been directly observed in
 229 mesospheric bores (e.g., Fritts et al., 2020).

230 Our sketch together with the spatial features shown in Figure 2 resembles the meso-
 231 spheric bore features of Bore 1 reported by Fritts et al. (2020), where they combined 2D
 232 images of PMC and lidar vertical profiling. As in the case of Fritts et al. (2020), we also
 233 expect that the observed vertical velocity divergence (convergence) ahead of (behind)
 234 the extreme event is accompanied by horizontal wind convergence (divergence). This hor-
 235 izontal wind behavior, unfortunately, could not be directly measured in our case. How-
 236 ever, using vertical velocities from Figure 1i and assuming an incompressible flow, the
 237 estimated local horizontal wind convergence is $\sim 14 \text{ ms}^{-1}\text{km}^{-1}$, which is more than 100
 238 times the measured mesoscale horizontal divergence in this region (Chau et al., 2017).
 239 Note that the large local horizontal wind convergence/divergence is expected at the cen-
 240 tral altitude and not where the high vertical velocities are observed.

241 The vertical dimensions of our event are more than two times larger than those re-
 242 ported by Fritts et al. (2020), i.e., $2h_1 \sim 13$ and $2h_0 \sim 3.0$ km, instead of 4.7 and 2.8 km,
 243 respectively, where $2h_1$ and $2h_0$ are the vertical extensions during the peak of the per-
 244 turbation and before the perturbation. These dimensions imply a normalized bore am-
 245 plitude $\beta = (h_1 - h_0)/h_0 \sim 3.33$ which is much larger than previously measured or in-
 246 ferred characteristics of mesospheric bores or wall waves (e.g., Taylor et al., 1995; Li et
 247 al., 2007; Smith et al., 2003, 2017). Vertical velocities in previous mesospheric bores have
 248 been expected or measured to be less than 10 ms^{-1} (e.g., Li et al., 2007).

249 Morphologically our extreme event resembles a mesospheric bore, but given its ver-
 250 tical dimensions, observed vertical velocities, and single observed crest, our event is unique.
 251 Unfortunately, temperature and density profiles are not available for this event. How-
 252 ever, as in the case of typical mesospheric bores, we expect that our event is a consequence
 253 of an instability occurring in some type of ducting (Doppler, thermal or a combination
 254 of both). Ducting regions are ubiquitous, but mesospheric bores are not. Possible mech-
 255 anisms that have been invoked to explain mesospheric bores might also explain our ob-
 256 servations, e.g., interaction of gravity waves with the mean flow at a critical level (e.g.,
 257 Dewan & Picard, 1998), non-linear internal gravity waves trapped within a thermal in-
 258 version layer (e.g., Seyler, 2005), etc. Interesting to note is that run 8 in Seyler (2005)

259 Table 1, reproduces a single-crest bore with larger amplitudes and Bore speeds than the
260 other runs. However, none of the previous theories aimed to explain an event with the
261 large β and very high vertical velocities that characterized our observations.

262 DNS results of stratified flows have predicted extreme vertical velocities localized
263 in space and time under particular values of stratification, specifically with Froude num-
264 ber $\sim 0.1-0.01$ (Feraco et al., 2018). Although a one-to-one comparison with our event
265 is difficult, the DNS results indicate that the resonant interaction between gravity waves
266 and turbulent motions responsible for the simulated DNS results, might play a role in
267 explaining our event. Such comparison with DNS results and possibly more events will
268 be pursued on a future work.

269 **4.3 How often mesospheric extreme events occur?**

270 We have presented only one event showing extreme vertical velocities. At this point
271 is difficult to infer if this is an isolated one-of-a-kind event, or if they occur more often
272 but, due to their high velocities and spatio-temporal characteristics, have been ignored.

273 In the case of previous PMSE observations with MAARSY, the great majority were
274 done with Nyquist velocities less than 30 ms^{-1} . Therefore, extreme drafts have been fil-
275 tered out and cannot be recovered by their velocity values. In cases where larger Nyquist
276 velocity have been used, they were presumably treated as outliers given their large val-
277 ues and relative short duration (e.g. Gudadze et al., 2019, Figure 4). In the latter cases,
278 a careful reprocessing should be pursued to search for additional extreme drafts. Data
279 obtained with small Nyquist might still be useful, if one looks for sudden vertical excur-
280 sions (up and down).

281 Based on the possible relation to mesospheric bores that have been observed at dif-
282 ferent latitudes (Hozumi et al., 2019), such extreme drafts are not expected to be unique
283 to the polar summer mesosphere. Thus, one should search for extreme vertical veloci-
284 ties at other latitudes, seasons, with a variety of instruments. For example, mesospheric
285 solitary waves (solitons) reported from foil chaff experiments in the past, might have sam-
286 pled a small spatial and temporal portion of an extreme event like the one reported here
287 (Widdel, 1991).

288 Although our work is focused on vertical velocities, such extreme events should show
289 up in other atmospheric variables, e.g., temperatures, airglow intensities, NLC bright-
290 ness, etc. As far as we know, extreme events based on these parameters have not been
291 reported so far, or they might have been ignored.

292 **4.4 Potential impacts**

293 In the particular case of the polar summer mesosphere, ice particles exist and they
294 are the main reason for the presence of NLC and PMSE (e.g. Thomas & Olivero, 1986;
295 Rapp & Lübken, 2004). Using expected temperature and pressure profiles from empiri-
296 cal models as well as the observed vertical drafts, we find that in our specific case the
297 temperature increases significantly in the downdraft regions. This increase causes the
298 reduction of ice particle radius in time scales of a few minutes (see Figure S1). In the
299 case of PMSE, their volume reflectivity is mainly determined by the Schmidt number,
300 which is proportional to the square of ice particle radius (e.g., Rapp & Lübken, 2004).
301 Therefore a reduction of ice particle radius would mean a weaker PMSE. In Figure 1a,
302 the strength of echoes decreases or echoes even disappear for the regions experiencing
303 downdrafts. In the updraft regions, the strength of echoes increases but based on our
304 calculations this increase is not related to the ice particle radius, instead it could be due
305 to an increase of electron density. These simple calculations indicate that indeed ice par-
306 ticle radius is affected by extreme vertical drafts, and so are clouds and echoes relying
307 on it.

308 Like in the case of ice particles, other mesospheric species would also experience
309 significant changes in altitude, and therefore their mixing ratios might change at a given
310 altitude. The transport of photochemically inactive species across the turbopause by ver-
311 tical winds enhances their concentration much more rapidly compared to turbulent mix-
312 ing, which implies that extreme vertical updrafts are an effective mechanism to trans-
313 port trace gases into the lower thermosphere. For example if Argon and molecular Ni-
314 trogen are brought to higher altitudes, e.g., from 90 to 110 km, it could take up to 3 h
315 to fully mix these components, i.e., much longer than if these species would have stayed
316 at 90 km (e.g., Von Zahn et al., 1990).

5 Conclusions

We report the first observations of extreme vertical drafts ($\pm 50 \text{ ms}^{-1}$) in the mesosphere characterized by a solitary wave behavior in varicose mode. Although their horizontal and spatial structures resemble those of previously observed mesospheric bores, our event shows only one crest with a much larger vertical extent than previous observations. This vertical extension is consistent with the observed extreme vertical velocities.

Our current poor knowledge on these extreme drafts (formation, occurrence rate, duration, predictability) as well as limited observing capabilities in the mesosphere, should not impede the exploration of impacts on other fields where km-scale perturbations and instabilities and high vertical drafts might be important. As in the case of mesospheric bores, if they occur frequently a better understanding and characterization would contribute to the roles of such dynamics (including small-scale gravity waves and instability dynamics) in a number of parameters requiring parameterization in large-scale general circulation weather and climate models (e.g., Fritts et al., 2014, 2020). Further observations as well as theory and modelling efforts are still needed to find and identify the specific sources of mesospheric bores and our reported event.

Acknowledgments

This work was partially supported by the Deutsche Forschungsgemeinschaft (German Research Foundation) under project LU1174/8-1 (PACOG) of the research unit FOR1898, and under SPP 1788 (CoSIP) project CH1482/3-1 (CS-PMSE-MIMO). The authors would like to thank Nikoloz Gudadze for suggesting us to look at the PMSE observations from July 16, 2016.

Open Research Data Statement

PMSE radar spectra and imaging data as well as meteor wind data, can be found here <https://www.radar-service.eu/radar/en/dataset/RD0yben0QktKPLsT?token=MIPFqNPRJY0xNGsasNXi>.

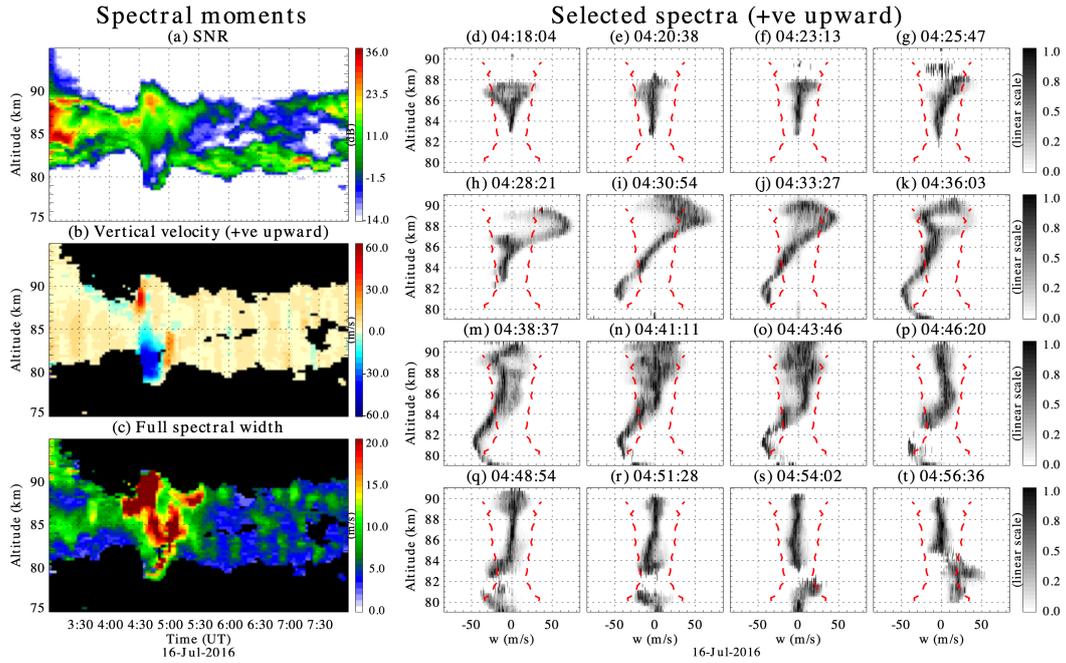

Figure 1. (Left) Range-time plots of: (a) signal-to-noise ratio (SNR), (b) vertical velocity (positive upward), and (c) total spectral width, observed with a vertical pointing beam on July 16, 2016. Note the relative large scales being shown for vertical velocities ($\pm 60 \text{ ms}^{-1}$). (Right) Normalized spectra as a function of w , where $w = -f\lambda/2$, f is Doppler frequency in Hz, and λ the radar wavelength in meters. The normalization is in power spectra amplitude for each altitude with respect to its maximum. Three-sigma levels ($3\sigma_w$) based on June–July 2016 observations are plotted in dashed red lines.

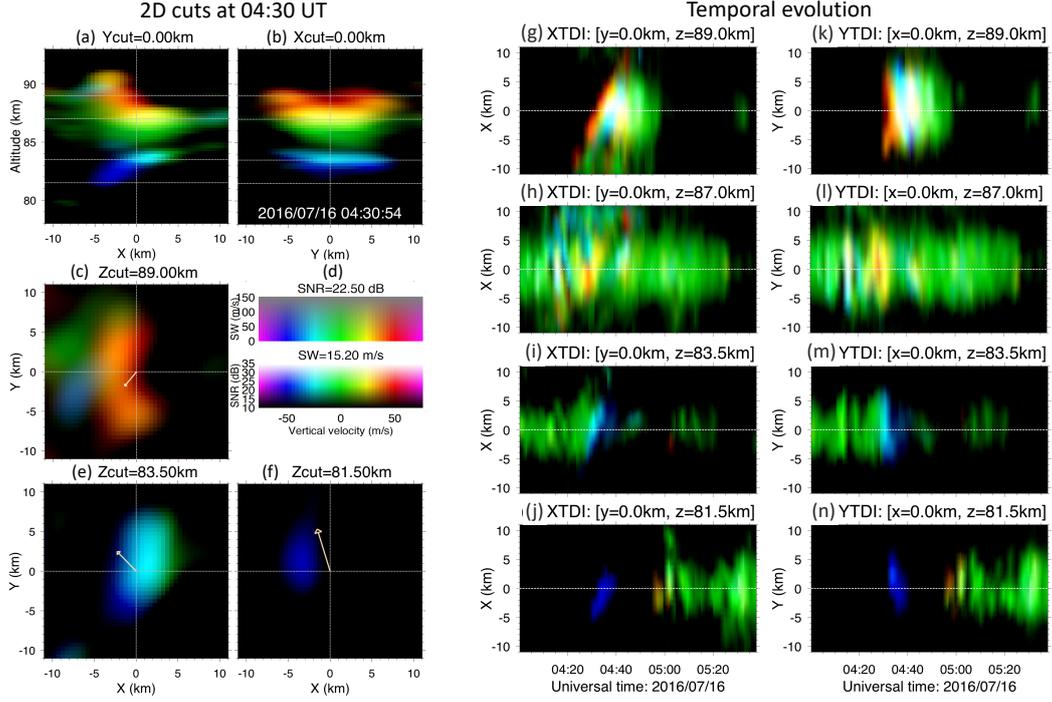

Figure 2. (Left) Two dimensional spatial cuts of PMSE inside the illuminated volume on July 16, 2016 around 0430 UT. xz and yz cuts at $x = 0$ and $y = 0$ km in panels (a) and (b), respectively. xy cuts at altitudes 89.0, 83.5, and 81.5 km in panels (c), (e), and (f), respectively. The intensity indicates signal strength of the echoes, while the color shows vertical velocity. Red (blue) values represent upward (downward) velocities greater (smaller) than 25 (-25) ms^{-1} , while green values represent velocities in between (see panel d). The 30-min horizontal wind from the specular meteor radar is indicated with a yellow arrow in the center of each xy cut. (Right) Space-time cuts at altitudes 89.0, 87.0, 83.5, and 81.5 km, of xy cuts in the left panel: (g-j) x versus time for $y = 0$, and (k-n) y versus time for $x = 0$.

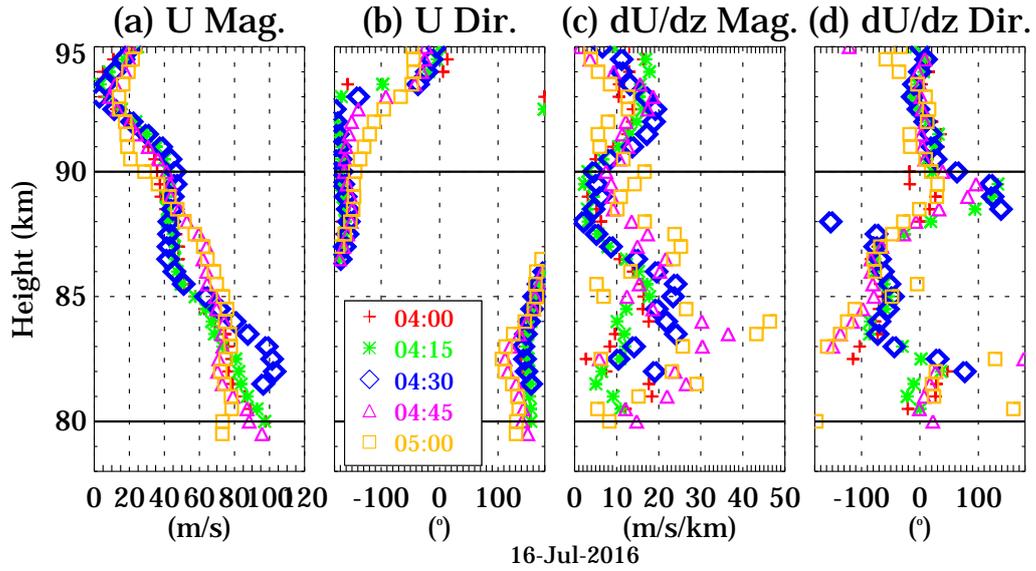

Figure 3. Horizontal winds profiles obtained with a collocated radar that observe specular meteor echoes around 04:30 UT on July 16, 2016: horizontal wind magnitude and direction with their respective vertical gradients. The direction is with respect to x , positive anti-clockwise. The colors indicate time in minutes with respect to 04:30 UT. The central time values are marked with black diamonds.

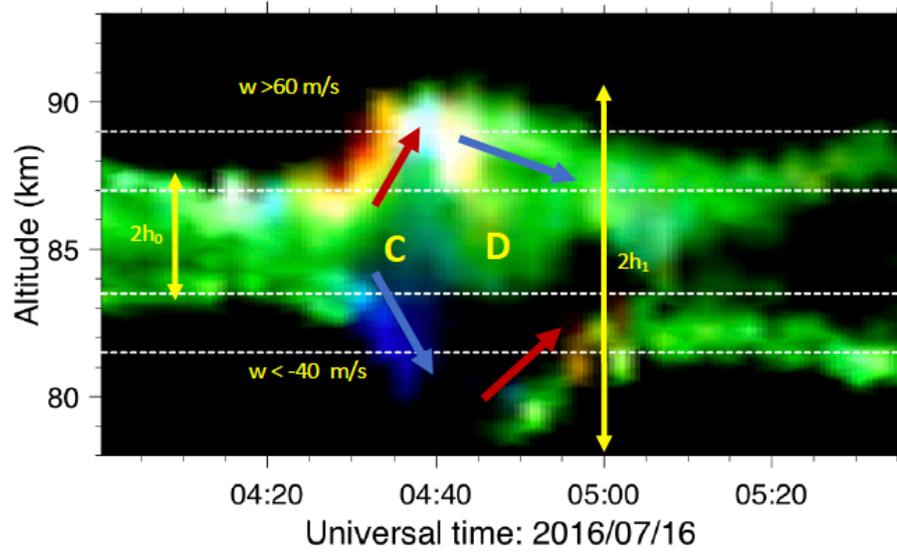

Figure 4. Closeup of the observations shown in Figure 1 to sketch the dynamics accompanying our event. The color code is the same as the one in Figure 2d. The regions of strong updraft (downdraft) are indicated with red (blue) arrows. Letter C and D represent horizontal wind convergence and divergence, respectively. Yellow vertical arrows indicate relevant vertical scales (see text).
