9 **Key Points**

- 10 • High-resolution reflection seismic data reveals that the internal architecture of the
11 Kolumbo Volcanic Chain
- 12 • The Kolumbo Volcanic Chain evolved during two episodes along NE-SW striking normal
13 faults
- 14 • A prominent volcanic ridge connects the Kolumbo Volcanic Chain with Santorini
15 highlighting a former connection between both systems

16 **Abstract**

17 The Christiana-Santorini-Kolumbo volcanic field in the southern Aegean Sea is one of the most
18 hazardous volcanic regions in the world. Forming the northeastern part of this volcanic field, the
19 Kolumbo Volcanic Chain (KVC) comprises more than 20 submarine volcanic cones. However,
20 due to their inaccessibility, little is known about the spatio-temporal evolution and tectonic control
21 of these submarine volcanoes and their link to the volcanic plumbing system of Santorini. In this
22 study, we use multichannel reflection seismic imaging to study the internal architecture of the
23 KVC and its link to Santorini. We show that the KVC evolved during two episodes, which initiated
24 at ~1 Ma with the formation of mainly effusive volcanic edifices along a NE-SW trending zone.
25 The cones of the second episode were formed mainly by submarine explosive eruptions between
26 0.7 and 0.3 Ma and partly developed on top of volcanic edifices from the first episode. We identify
27 two prominent normal faults that underlie and continue the two main trends of the KVC, indicating
28 a direct link between tectonics and volcanism. In addition, we reveal several buried volcanic
29 centers and a distinct volcanic ridge connecting the KVC with Santorini, suggesting a connection
30 between the two volcanic centers in the past. This connection was interrupted by a major tectonic
31 event and, as a result, the two volcanic systems now have separate, largely independent plumbing
32 systems despite their proximity.

33 **Plain Language Summary**

34 In the central Aegean lies the Christiana-Santorini-Kolumbo volcanic system, one of the most
35 volcanically and seismically active regions in Europe. Santorini has had over 200 eruptions in
36 the last 360,000 years. Only 7 km northeast of Santorini lies the underwater volcano Kolumbo,
37 as well as over 20 other smaller underwater volcanoes that form the Kolumbo Volcanic Chain,
38 which have only had 2 major eruptions during this time. In this study, we investigate the history
39 of this volcanic system to understand its relation to Santorini and why volcanoes located so
40 closely together behave so differently. Using seismic reflection data image the internal

41 architecture of the Kolumbo Volcanic Chain and show that it evolved in two episodes along two
42 prominent faults that might continue underneath Santorini. We also identify a volcanic ridge that
43 lies between Santorini and Kolumbo, indicating a connection between the two systems. Our
44 study suggests that Santorini and the Kolumbo Volcanic Chain evolved as one system in the
45 geological past, but became disconnected from each other during a major tectonic event about
46 300,000 years ago.

47 **1 Introduction**

48 Violent explosive eruptions at volcanic arcs account for ~95% of all eruption-related fatalities
49 since 1600 CE, many associated with eruptions of coastal or marine volcanoes (e.g., Krakatau, or
50 Tambora; Auker et al., 2013; Brown et al., 2017). As recently demonstrated by the 2022 eruption
51 of Hunga Tonga–Hunga Ha‘apai, seawater interaction during shallow eruptions is capable of
52 producing violent phreatomagmatic explosions that generate ocean-scale tsunamis (Carvajal et al.,
53 2022; Lynett et al., 2022). In arc settings, magma is generated by partial melting of the mantle
54 above the subducting slab, and its ascent to the surface is governed by thermodynamic conditions
55 within the crust (e.g., Cashman & Sparks, 2017). Volcanic plumbing systems represent a complex
56 network of vertically extensive melt reservoirs at different depths, developed over long timescales
57 during the growth of a volcano (e.g., Tibaldi & Bonali, 2017). At shallow depths, magma rises
58 along faults and fractures influenced by the regional tectonic stress state, which can lead to the
59 formation of volcanic lineaments (e.g., Tibaldi, 1995). Magma path orientation can be stable over
60 long time scales but modifications in the tectonic stress regime, such as from large earthquakes or
61 modifications in volcano morphology, can influence the volcanic plumbing system (e.g., Hill et
62 al., 2002). This can lead to temporal changes in the eruptive style of individual volcanoes or over
63 short distances from one volcano to another (e.g., Hill et al., 2002).

64 Investigating the spatio-temporal evolution of the orientation of volcanic plumbing systems is
65 important for understanding the behavior of active volcanoes (e.g., Tibaldi & Bonali, 2017). Being
66 hidden beneath the surface, the deep structure and temporal evolution of volcanic plumbing
67 systems can only be assessed on the basis of geochemical constraints (e.g., Druitt et al., 2012), by
68 studying eroded volcanoes (e.g., Tibaldi et al., 2013) or indirectly via geodetic monitoring (e.g.,
69 Bato et al., 2018). However, these methods are difficult to apply to submarine volcanoes due to
70 their inaccessibility for direct sampling and monitoring (Carey & Sigurdsson, 2007; Mitchell
71 2012). Here, geophysical methods are required, and recent advances in seismic tomography and
72 full-waveform inversion enable the imaging of shallow melt reservoirs underneath active
73 volcanoes (e.g., Paulatto et al., 2022), but often lack the resolution required to reconstruct the
74 temporal evolution of the system. This critical observational gap can be addressed by high-
75 resolution multichannel seismic imaging, which provides structural images of the subsurface that
76 can be used to reconstruct the relative spatio-temporal evolution of submarine volcanic systems
77 (e.g., Preine et al., 2022a).

78 One of the few areas worldwide, where crustal-scale and high-resolution geophysical data as well
79 as detailed petrological analyses are available, is the Christiana-Santorini-Kolumbo (CSK)
80 volcanic field in the southern Aegean Sea (Fig. 1) (Nomikou et al., 2019). This 60-km-long
81 volcanic field has produced over 200 eruptions in the last 360 thousand years, including the famous
82 Minoan eruption of Santorini 1600 BCE (e.g., Druitt et al., 1999; Nomikou et al., 2016a; Satow et
83 al., 2021). Located only 7 km northeast of Santorini lies the submarine Kolumbo volcano, which

84 last erupted in 1650 CE, causing ~70 fatalities on Santorini and generated a tsunami that inundated
85 the nearby Cycladic islands (Fouque, 1879; Cantner et al., 2014; Karstens et al., In Review_A).
86 This eruption created a 500 m deep and 1500 m wide crater, which hosts an active hydrothermal
87 vent field (Carey et al., 2011; 2013; Fuller et al., 2018). Kolumbo consists of five vertically stacked
88 volcanic units (Hübscher et al., 2015) and is the largest volcano of the Kolumbo Volcanic Chain
89 (KVC), which itself consists of more than 20 submarine volcanoes that are aligned along two NE-
90 SW striking lineaments 16 km northeast of Kolumbo (Nomikou et al., 2012; Hooft et al., 2017).

91 Since the entire CSK field lies in the same regional rift system, it is subject to a common external
92 tectonic control (e.g., Heath et al., 2019; 2021; Preine et al., 2022c). There is an ongoing discussion
93 regarding the role of regional (> 10 km length) and local (< 10 km length) faults on the
94 emplacement of volcanic features (Hübscher et al., 2015; Heath et al., 2021) and regarding the
95 connection of the plumbing system between the different volcanic centers. While geochemical
96 analyses of the eruption products from both volcanoes suggest independent crustal differentiation
97 (Klaver et al., 2016; Rizzo et al., 2016), seismic tomography showed the presence of a low-velocity
98 anomaly connecting Santorini and Kolumbo at a depth of 3-5 km, interpreted as a zone of
99 magmatic intrusions (Heath et al., 2019; McVey et al., 2020). To date, it is not clear whether there
100 is further evidence for a link between the Santorini volcanic system and the Kolumbo Volcanic
101 Chain, nor is it known how their plumbing systems have evolved in time and space. To address
102 these questions, in this study we investigate the internal architecture of the volcanic edifices from
103 the KVC and explore their relationship to the regional tectonic system using seismic reflection
104 images. Furthermore, we investigate seismic reflection evidence for volcanic features in the area
105 between Santorini and Kolumbo. Based on these analyses, our objectives are to (1) reconstruct the
106 spatio-temporal evolution of the Kolumbo Volcanic Chain, and (2) investigate whether there is a
107 link between the evolution of Santorini and the Kolumbo Volcanic Chain.

108 **2 Geological Framework**

109 The KVC is part of the CSK volcanic field, one of the most active volcano-tectonic regions in the
110 Mediterranean Sea (e.g. Bohnhoff et al., 2006; Nomikou et al., 2019). Formed by the partial
111 melting of the subducting African slab beneath the Eurasian plate, volcanism along the CSK field
112 evolved in four phases, which initiated in the Late Pliocene with the emergence of the Christiana
113 Volcano southwest of present-day Santorini (Phase 1; Piper et al., 2007; Preine et al., 2022a). The
114 subsequent formation of major NE-SW trending fault systems in Middle Pleistocene correlates
115 with the emergence of the early Kolumbo and Poseidon centers (Phase 2), which deposited
116 volcanoclastic material in the Christiana and Anhydros Basins, respectively (Hübscher et al., 2015;
117 Preine et al., 2022a; 2022c). The KVC is thought to have formed after a major tectonic pulse that
118 triggered a cascade of large-scale mass-wasting events at Santorini and Kolumbo (Phase 3; Preine
119 et al., 2022b; 2022c). This series of events marks the beginning of the third phase, which is thought
120 to include not only the formation of the KVC, but also buried volcanic cones southwest of
121 Santorini, and the evolution of the onshore exposed Akrotiri rhyolitic center, the Peristeria
122 stratovolcano, and the Akrotiri cinder cones (Druitt et al., 1999; Preine et al., 2022a). In the last
123 phase (since ~360 ka; Phase 4), a major tectonic event occurred in the Santorini-Anafi Basin,
124 followed by the onset of highly explosive volcanism at Santorini, which corresponds to a distinct
125 change in the primitive melt diversity (Flaherty et al., 2022). This explosive volcanism formed the

126 Thera Pyroclastic Formation, while Kolumbo remained active producing two major eruptions
127 (Preine et al., 2022a, 2022c).

128 Kolumbo's five units (K1-K5) formed over the course of more than 1 million years (Hübscher et
129 al., 2015; Preine et al., 2022a). Seismic reflection data have shown that these volcanic units
130 generally have low-amplitude internal reflections, indicating that they were formed by explosive
131 underwater eruptions (Hübscher et al., 2015). This is consistent with ROV surveys of the crater
132 walls, which show they consist of over 250 m of pumice lapilli and pumice block breccias
133 produced by the historic 1650 CE eruption (Carey et al., 2011). Presently, a hydrothermal vent
134 field is still active in the northern part of the Kolumbo crater (Carey et al., 2011; 2013), and
135 frequent swarms of microseismicity indicate ongoing melt ascent (Schmid et al., 2022) from a melt
136 reservoir at ~2 to 4 km below the crater (Chrapkiewicz et al., 2022).

137 Northeast of Kolumbo, volcanoes within the KVC occur in water depths of up to 450 m, with
138 summit heights of up to 200 m above the surrounding seafloor (Nomikou et al., 2012). Most of
139 these volcanoes are cone-shaped, with some having characteristic craters at the top, while most
140 have smooth, rounded summits (Fig. 1c) (Nomikou et al., 2012; Hooft et al., 2017). The cones of
141 the KVC are aligned along two main trends that are approximately linear and NE-SW oriented
142 (orange dotted lines in Fig. 1d), lying parallel to the main fault trend of the CSK rift zone (Nomikou
143 et al., 2012; Hübscher et al., 2015). Only two volcanoes (VC8 and VC16) lie off these main
144 lineaments (Fig. 1c). ROV surveys revealed that the volcanoes are sediment-covered and show
145 little to no evidence of recent volcanic activity (Nomikou et al., 2012). Volcanic rock outcrops on
146 the cones consist of fragments of pumice and lava that have been cemented by biological activity,
147 while some show evidence of recent low-temperature hydrothermal activity (Nomikou et al.,
148 2012). In general, the bases of the slopes consist of fine-grained material, while the upper slopes
149 consist of pumice clasts and scattered lapilli (Nomikou et al., 2012; Carey et al., 2013). Previous
150 seismic surveys of some of the volcanic cones revealed low-amplitude reflections within the
151 volcanic cones, which were interpreted as volcanoclastic material from explosive eruptions similar
152 to those that formed the Kolumbo volcano (Hübscher et al., 2015).

153 An important influence of the local tectonic system on the emplacement of volcanoes at the CSK
154 field has been suggested by previous studies due to the overall linear alignment of volcanic edifices
155 parallel to the NE-SW striking regional rift system (e.g., Druitt et al., 1999; Dimitriadis et al.,
156 2009; Feulliet, 2013, Heath et al., 2019; 2021; Preine et al., 2022c). The two most prominent
157 volcano-tectonic lineaments are the Kameni and Kolumbo lines, which strike NE-SW intersecting
158 the northern part of the Santorini caldera (Fig. 1a) (Druitt et al., 1999; Heath et al., 2019; Hooft et
159 al., 2019; McVey et al., 2020) (Fig. 1a). While the Kameni line is defined by a linear alignment of
160 post-Minoan vents in the center of the caldera, the Kolumbo line connects older volcanic centers
161 in the northern caldera basin and extends towards Kolumbo (Fig. 1a). Both lineaments bound a
162 region of isolated caldera collapse (Hooft et al., 2019) as well as a low-velocity anomaly in the
163 depth of 3 to 5 km that extends from the northern caldera basin towards Kolumbo (Heath et al.,
164 2019; McVey et al., 2020).

165 **3 Methods**

166 In this study, we utilize an extensive dataset of more than 3,200 km of high-resolution multi- and
167 single-channel seismic data acquired during six cruises between 2006 and 2019 (Fig. 1b)
168 (Sigurdsson et al., 2006; Hübscher et al., 2006; Karstens et al., 2020). For all multichannel seismic

169 lines, we applied multiple removal by means of surface-related multiple elimination and pre-stack
170 time migration to improve the quality of the seismic images. More details on the acquisition and
171 processing of the seismic data can be found in *Supplementary Information S1*. All processed
172 seismic lines were combined into an interpretation project using the Kingdom Suite software. In
173 Figure 4, we use instantaneous phase plots (Taner et al., 1979) to highlight low-amplitude but
174 coherent events within the volcanic edifices.

175

176 **4 Seismic interpretation**

177

178 4.1 Seismo-stratigraphic framework

179

180 To establish a relative chronology of the evolution of the KVC, we use the seismo-stratigraphic
181 framework established in Preine et al. (2022a, b). This framework consists of six units separated
182 by six key horizons h1-h6. Unit 1 overlies the acoustic basement and consists of sub-parallel
183 reflections of very low amplitude, which are often difficult to image due to the overprint of the
184 seafloor multiple. The overlying Unit 2 consists of a series of well-stratified reflections with low
185 to medium amplitudes. Units 3 and 5 consist of a series of well-stratified medium amplitude
186 reflections. In contrast, Unit 4 consists of chaotic, weakly reflective material that has been
187 interpreted as the deposits of the Santorini mass wasting cascade (Preine et al., 2022b). Where
188 Unit 4 is missing, Unit 5 directly overlies Unit 3. The uppermost Unit 6 consists of high amplitude
189 reflections that become irregular near Santorini, where they comprise the deposits of the Thera
190 Pyroclastic Formation (Preine et al., 2022a). For the interpretation of the volcanic units of
191 Kolumbo, we follow the nomenclature of Hübscher et al. (2015), who labeled the Kolumbo Units
192 K1-K5.

193

194 4.2 Kolumbo Volcano and the Kolumbo Volcanic Chain

195

196 Figure 2 shows two seismic profiles crossing the Kolumbo Volcano perpendicular to each other.
197 The uppermost profile crosses the Anhydros Basin and Kolumbo in the NW-SE direction (Fig.
198 2a). In the Anhydros Basin, we identify all seismo-stratigraphic Units, which have relatively
199 constant thicknesses. There are several faults intersecting the strata of the Anhydros Basins, with
200 the Kolumbo Fault being the most prominent (as shown also in Nomikou et al., 2016b; Preine et
201 al., 2022a). On top of the uppermost Unit U6, we identify a chaotic subunit, which thickens
202 towards Kolumbo and represents the Minoan ignimbrites (yellow semi-transparent area)
203 (Hübscher et al., 2015; Karstens et al., In Review_B). This Unit is overlain by Kolumbo's Unit
204 K5, which consists of well-stratified reflections representing the pumice deposits of the 1650 CE
205 eruption (Cantner et al., 2014; Hübscher et al., 2015; Karstens et al., In Review_A). Kolumbo's
206 Unit K4 lies at the basis of Unit U6 and consists of chaotic to transparent internal reflections (Fig.
207 2a). K3 is comparatively small and intercalated within Unit U5, while K2 makes up most of the
208 Kolumbo edifice and is partly exposed on the crater wall (Fig. 2b). Both K2 and K1 are intercalated
209 within Unit U3 and separated from each other by prominent high-amplitude reflections (Fig. 2a).
210 In the center of the Kolumbo crater, we identify an acoustically transparent structure, which
211 represents a dyke that is exposed on the crater wall (Karstens et al., In Review_A).

212

213 The profile in Figure 2b starts on the eastern flank of Santorini, crosses the Kolumbo crater, and
214 eight additional cones of the KVC. On the flank of Santorini, we identify the Minoan ignimbrites,

215 which have a wavy topography typical for submarine pyroclastic flow deposits (Pope et al., 2018).
216 Horizon h6 marks a distinct onlap surface, onto which most of the internal reflections of Unit 6
217 terminate (orange arrows, Fig. 2b). Unit 4 is absent in this profile and the deeper Units 1-3 are
218 difficult to interpret since the seismic image is disturbed in the deeper part, especially below the
219 KVC or towards Santorini (Fig. 2b). At profile kilometer 2.5, we identify a high-amplitude
220 reflection within Unit 4 (red dashed line, Fig. 2b), causing acoustic blanking underneath, which
221 may indicate a small volcanic edifice (Fig. 2b).

222 Beneath Kolumbo, we identify the Kolumbo Units K1, K2, K4, and K5. Unit K4 is relatively small
223 here, while K3 appears to be absent. On the southwest side of Kolumbo, the termination of K2 and
224 K1 is well imaged (~km 5, Fig. 2b). However, the termination towards the northeast below the
225 KVC cannot be constrained as the seismic image becomes highly disturbed below the KVC.

226 The cones of the KVC crossed in this profile decrease in height towards the NE and display
227 complex onlapping relationships with each other (Fig. 2b). In general, the cones have an internal
228 architecture similar to that of Kolumbo, consisting of stratified flanks with weak seismic
229 amplitudes and a chaotic, weakly reflective core (Fig. 2b). The cones are located on top of weakly
230 reflective strata with several high amplitude reflections (purple semi-transparent area, Fig. 2b).
231 Underneath VC2 and VC6, we observe a zone of vertically pervasive blanking and velocity pull-
232 up (marked 'blanking' in Fig. 2b), which is a typical effect occurring beneath high-velocity
233 volcanic rocks within a sedimentary sequence (e.g., Jackson, 2012; Magee et al., 2013b; Reynolds
234 et al., 2018). Beneath VC6, we observe a sequence of well-stratified reflections that onlap a cone-
235 shaped, acoustically transparent area (orange triangles, Fig. 2b).

236
237 Figure 3 shows three seismic profiles traversing the central part of the KVC. The uppermost profile
238 crosses the Anhydros Basin and the southwestern part of the KVC including VC6, VC5, and VC3
239 (Fig. 3a). In the Anhydros Basin, we identify all six seismostratigraphic units and the Ios and
240 Kolumbo Faults to the NW of the KVC. Between the Kolumbo Fault and the KVC is a complex
241 fault zone with several small offset internal faults that terminate within Units 3 and 4 (Fig. 3a).
242 Southeast of the KVC, towards the Anhydros Horst, we observe additional internal faults. The
243 flanks of the volcanic cones are all intercalated with Unit 5. There is a zone of pronounced seismic
244 blanking and velocity pull-ups beneath the central part of VC5, while underneath VC6, we identify
245 a zone of chaotic, low amplitude reflections (purple semi-transparent area, Fig. 3a). The reflections
246 from Unit 5 overly and/or onlap this cone-shaped area (km 15 in Fig. 3a). It is noteworthy that the
247 base of e.g. VC5 lies approximately 130 ms beneath the seafloor, implying that the total height of
248 VC5 is about 115 m greater than the 200 m protruding upwards from the seabed (assuming a
249 velocity of 1750 m/s for unit 6 and 1500 m/s as water velocity, Preine et al. (2022a)).

250 The seismic profile in Figure 3b crosses the Ios Fault and the deep part of the Anhydros Basin,
251 where we find all six seismostratigraphic units and several internal faults (Fig. 3b). The profile
252 crosses the flanks of VC5 and VC11 as well as VC7 and VC8. While VC5 and VC11 cause no
253 pull-up or acoustic blanking indicating a moderate internal velocity of the flanks, VC7 and VC8
254 cause complete blanking of the underlying strata except for some scattered reflection patches
255 (purple dashed lines, Fig. 3b). The margin of the Anhydros Basin and the Anhydros Horst is not
256 resolved due to the acoustic blanking (Fig. 3b). Figure 3a shows that VC7 onlaps VC8, while the

257 northwestern flank of VC7 occurs within Unit 3, suggesting an older age for these two cones
258 compared to the other cones of the KVC, which are within Unit 5 (Preine et al., 2022a) (Fig. 3b).

259 The seismic profile in Figure 3c is similarly oriented to the profile crossing the Ios Fault and the
260 Anhydros Basin. Figure 3c crosses VC16, which is slightly further west than the rest of the KVC
261 (Figs. 1, 3c). We identify high amplitude and irregular reflections at the top of this edifice (VC16)
262 and pronounced acoustic blanking underneath (Fig. 3c). This is in contrast to the flanks of VC5
263 and VC11 (Fig. 3b) or VC5 and VC6 (Fig. 3a), where the acoustic blanking is much less
264 pronounced and we can identify reflections below the cones. On the other hand, the acoustic
265 characteristics of VC16 are similar to those of VC7 and VC8 (Fig. 3b), where complete acoustic
266 blanking is observed. Furthermore, Figure 3c shows that below VC12, the reflections of Unit 3
267 onlap a body of chaotic/transparent internal reflections, which is connected to a broad zone of
268 pronounced acoustic blanking beneath VC9 and VC8 (purple semi-transparent area in Fig. 3b).
269 Similar to Figure 3b, the transition from the Anhydros Basin to the Anhydros Horst is not resolved
270 in this profile (Fig. 3c).

271 The profiles shown in Figures 2 and 3 highlight that the internal architecture of the different
272 volcanic edifices of the KVC is diverse. To examine this in more detail, Figure 4 shows
273 enlargements of selected volcanoes from the KVC with their respective instantaneous phase
274 representations, which reveal weak coherent events within the volcanic edifices. We identify the
275 following three main characteristic features:

276 **Seismic Facies 1 (SF1):** Many volcanic cones have well-stratified flanks with a pronounced
277 downlap termination towards the base of the edifice (VC3, VC6, VC11, and VC12) (Fig. 4). While
278 these reflections have low amplitudes and are barely visible in the amplitude plots (Fig. 4a, c, e),
279 they are visible as coherent closely-spaced reflections in the instantaneous phase plots (Fig. 4b, d,
280 f). Similar stratified flanks can be observed within Unit K5 of Kolumbo (Fig. 2a, b), where they
281 represent stratified pumice deposits of the explosive 1650 eruption (Hübscher et al., 2015; Karstens
282 et al. In Review_B). Based on the similarity between the stratified flanks of the volcanic cones and
283 the internal structure of Kolumbo's unit K5, we interpret that stratified flanks of the cones are
284 seismic indicators of pumiceous deposits and are thus indicative of explosive eruptions.

285 **Seismic Facies 2 (SF2):** All of the volcanic cones investigated in this study exhibit regions of
286 incoherent seismic facies, which we will refer to as SF2. While SF2 is visible as acoustically
287 blanked areas in the amplitude plots (Fig. 4a, c, e), the instantaneous phase plots show chaotic,
288 incoherent internal reflections (Fig. 4b, d, f). We identify SF2 in the central area of the volcanic
289 cones close to the vents (VC6, VC11) (Fig. 4), or within some of the acoustically transparent
290 structures below the cones, e.g., below VC6 or VC12 (Fig. 6). In several instances, the incoherency
291 of the strata cannot be explained by velocity effects from the overlying structures alone, as e.g.,
292 below VC6, individual horizons can be clearly imaged and traced underneath the volcanic cone,
293 showing a distinct onlap behavior to the underlying incoherent region, which itself has a cone-like
294 shape (Fig. 4a, b). This suggests that these features are buried volcanic structures over which newer
295 volcanic cones have developed. This is evident beneath VC12, where the flank of the buried edifice
296 is intercalated within Unit U3 (Fig. 3c, 4e, 4f). This acoustic signature could be explained by the

297 presence of brecciated material and massive hyaloclastites in the near-vent region of volcanic
298 edifices, which has been identified by ROV surveys in the summit regions (Nomikou et al., 2012).

299 We also identify the incoherent seismic facies along broader areas, e.g., within VC8 and VC16
300 (Fig. 6), where chaotic or acoustic blanking facies extend laterally over an area > 1 km. Below
301 these edifices, there is complete seismic blanking and no coherent reflections can be identified in
302 either the amplitude plot or the instantaneous frequency plot. This is in contrast to other volcanoes
303 of the KVC (e.g., VC3, VC6, and VC12) (Fig. 6), where reflections can be identified over wide
304 areas, also below the edifices, suggesting that VC8 and VC16 consist of a different, denser
305 material, e.g. lava flows.

306 **High amplitude reflection (HAR):** We identify several reflections with anomalously high
307 amplitudes compared to background reflectivity in the vicinity of several volcanic cones, e.g. next
308 to VC11 (Fig. 4c-f), or at VC16 (Fig. 4e, f). Some of these reflections, occurring directly beneath
309 volcanic cones, are saucer-shaped and phase-reversed and could be interpreted as sill intrusions
310 (e.g., Planke et al., 2006; Magee et al., 2016) (e.g., Figs. 4e, f). High-amplitude reflections without
311 phase reversals occur e.g. at VC11 directly below the crater (Fig. 4a, b), or at VC16 directly above
312 the acoustically blanked area (Fig. 4e, f) and could be related to the presence of effusive lava flows
313 as mentioned above.

314 4.3 The northeastern section of the Kolumbo Volcanic Chain

315 Figure 5 shows five profiles crossing the northeastern KVC and the transition to the non-volcanic
316 eastern Anhydros Basin. In all of these profiles, we identify three major normal fault systems Ab1-
317 Ab3, which all dip towards the southeast. The seismic profile shown in Figure 5a crosses VC17
318 and VC18, two of the easternmost cones of the KVC. Northwest of these volcanoes, we identify a
319 broad zone of strong acoustic blanking that appears to be associated with the northeastern flank of
320 VC16 (Fig. 5a). This acoustic blanking zone is overlain by Units 4-6, which appear to be uplifted
321 (Fig. 5a). While the thickness of Unit 5 above this zone is constant, Unit 6 is very thin, suggesting
322 that the uplift occurred prior to the deposition of Unit 6. Several faults are visible on the
323 southeastern margin of the Anhydros Basin, including the two prominent faults Ab1 and Ab2,
324 which can be traced along several profiles. Fault Ab1 offsets the seafloor, while Fault Ab2 shows
325 a major throw offsetting the acoustic basement by up to 150 meters, which is also visible in the
326 seismic profiles in Figures 5b and 5c. The volcanic edifices VC17 and VC18 appear to be located
327 in a zone with several faults that might continue underneath these cones, although these could also
328 be the result of acoustic disturbance due to the overlying volcanic cones (dashed lines and question
329 marks, Fig. 5c). This is also the case in the seismic profile in Figure 5b crossing VC18, which
330 seems to be located above several faults (dashed lines and question marks, Fig. 5b). VC20, which
331 is imaged in the seismic profile in Figure 5c, is located further to the NE and we identify Fault
332 Ab2 directly below the edifice, indicating a major structural relationship between the fault and the
333 edifice (Fig. 5c).

334 Overall, the sediment thickness in the profiles in Figures 5a-d decreases towards the northeast, and
335 only Units 3-6 are visible in the profile in Figure 5e, which is also devoid of volcanic structures.
336 We identify Fault Ab2 and Ab3 in the center of the basin, and towards Fault Ab2, the internal
337 reflections of Unit 3 are divergent (Fig. 5d). The seismic profile in Figure 5e crosses the eastern
338 Anhydros Basin, which represents a typical half-graben. The internal reflections of Units 2-4

339 thicken significantly towards the basin-bounding Ios Fault (Fig. 5e). We identify Faults Ab1 and
340 Ab2 in the central and eastern part of the Anhydros Basin, while Fault Ab3 appears to be absent
341 here.

342 4.4 The area between Kolumbo and Santorini

343 Figure 6 shows three seismic profiles traversing the Anhydros Basin between Kolumbo and
344 Santorini. The first profile extends from the northeastern flank of Santorini, crossing Kolumbo and
345 the Anhydros Horst (Fig. 6a). Similar to the profiles in Figure 2, we identify the Minoan deposits
346 on the flank of Santorini (semi-transparent yellow color; Fig. 6a). At profile kilometer 10, there is
347 a cone-shaped area of acoustic blanking (labeled 'Oia cone' in Fig. 6a). The internal reflections of
348 Unit 6 onlap this feature and, since we observe a velocity pull-up beneath, we interpret this feature
349 as a small buried volcanic cone similar to the Aspronisi cones southwest of Santorini (Preine et
350 al., 2022a). Continuing towards Kolumbo (at km 12), we observe a high amplitude reflection with
351 acoustic blanking beneath, at the boundary between Units 3 and 4 (red dashed lines, Fig. 6a). This
352 feature is very similar to the feature observed on the flank of Santorini in Figure 2b. At Kolumbo,
353 we identify all five Kolumbo Units and K3 represents a well-defined volcanic cone within Unit 5.
354 It is noteworthy that the summit of K3 is located about 3 km away from the crater of Kolumbo and
355 there is pronounced acoustic blanking below the center of the cone (km 15 in Fig. 6a).

356 Figures 6b and 6c show two profiles that are located further to the southwest, traversing the area
357 between Kolumbo and the northeast flank of Santorini. The profiles cross the Kolumbo Ridge,
358 which is a previously unrecognized morphological feature that extends for 6 km from the
359 northeastern flank of Santorini towards Kolumbo (Fig. 1c). Compared to the other profiles, the
360 strata here are more irregular, which is why some of the key horizons are indicated by dashed lines
361 (Figs. 6b, c). In both profiles, we identify the Minoan eruption deposits as the shallowest subunit
362 (Figs. 6b, c). The center of both profiles is dominated by a broad zone of pronounced acoustic
363 blanking (semi-transparent purple area) and upwardly bent reflections with some scattered high
364 amplitude reflections (marked by dashed purple lines in Figs. 6b, c). While the lower units U1-U3
365 cannot be traced along these zones of strong acoustic blanking, the upper units appear to partially
366 overlie the zone of acoustic disturbance, although it is difficult to trace reflections along these
367 zones. Only for the reflections of Unit 6 can we identify some onlap terminations towards horizon
368 h6.

369

370 5 Discussion

371 5.1 Spatio-temporal evolution of the Kolumbo Volcanic Chain

372 Using our seismo-stratigraphic framework, we are able to establish a relative spatio-temporal
373 model for the KVC. While the intercalation of the flanks of volcanic cones within the seismo-
374 stratigraphic units allows us to place them in the general stratigraphic framework of the CSK field
375 from Preine et al. (2022a), onlap terminations of individual cones against each other allow us to
376 place them into a relative age context as summarized in Figure 7a. For example, the following
377 relative age trend (becoming younger left to right) can be determined from onlap terminations
378 identified in the seismic profile in Figure 2b: VC2>VC4>VC6>VC3 (Fig. 7a). However, this

379 approach is limited to cones where our seismic data allow us to identify direct onlap terminations.
380 Volcanic edifices that are not imaged by our data or that are too far away from each other cannot
381 be integrated into this relative chronological framework, since internal reflections cannot be
382 reliably traced along the often chaotic or discontinuous intra-volcanic areas.

383 Our analysis shows that the evolution of the KVC is much more complex than previously thought
384 (Fig. 7a). According to the age model from Preine et al. (2022a), the Kolumbo cones evolved in a
385 single phase during the deposition of Unit 5 and are thus between approximately 0.7 and 0.36 Myrs
386 old (phase 3). However, Figure 3b clearly shows that VC7 and VC8 occur within Unit 3 and thus
387 evolved during the same phase as K1 and K2 from Kolumbo, implying an age of approximately 1
388 Myrs (Preine et al., 2022a). The buried edifices, e.g., below VC6 and VC12 (Fig. 3a, e) also appear
389 to have developed during this older phase indicating volcanism was widespread at that time. In
390 addition, our seismic images show that the internal architecture of these early volcanic edifices is
391 mainly composed of the incoherent seismic facies SF2 and that there is strong acoustic blanking
392 underneath, which is particularly evident at VC8 (Figs. 3b, 3c, 5c, 5d). As mentioned above, this
393 implies that the edifices from this phase are composed of a very dense, acoustically attenuating
394 material, that could be explained by the presence of thick effusive lava flows. This is in contrast
395 to most of the volcanoes of the younger phase, which were formed during the deposition of Unit
396 5 (~0.7-0.35 Ma) (Fig. 7a) and appear to have been formed primarily by explosive submarine
397 volcanism, as indicated by the seismically well-imaged flanks (Fig. 4) that are very similar to the
398 pumice-bearing crater walls of Kolumbo (Carey et al., 2011).

399 Onlap terminations from several cones of the KVC allow us to establish a relative chronological
400 model of the evolution of the KVC (Fig. 7a) and the spatial dimension of onlap terminations is
401 indicated in Figure 7b. However, not all volcanoes of this phase seem to have been formed by
402 explosive eruptions, since the seismic image of VC16 is more indicative of effusive volcanism due
403 to the strong acoustic attenuation below and the irregular high-amplitude reflections above (Figure
404 3c, 4e, 4f). The seismic profile in Figure 3c suggests that Unit 6 and parts of Unit 5 lie above
405 VC16. This is also corroborated by Figure 6a, where we interpret the acoustically disturbed zone
406 to be an intrusion related to VC16. Here, large parts of Units 4 and 5 appear to be uplifted, with
407 the lack of thickness variation of these units suggesting that this uplift occurred after their
408 deposition (Fig. 6a). In contrast, Unit 6 has a much lower thickness above this area, suggesting
409 that it was deposited after the evolution of VC16 (Fig. 6a). Thus, our analysis suggests that VC16
410 was formed during the deposition of Unit 5 and therefore belongs to Phase 3 of Preine et al. (2022a)
411 (Fig. 7a), which, accordingly, saw more diverse volcanism than the formation of monogenetic
412 cones only. Figure 7c shows a conceptual cross-section through the central part of the KVC,
413 highlighting the different types of volcanic edifices from the two episodes of KVC evolution. The
414 early phase saw the formation of the mainly effusive volcanic edifices such as VC8 and the buried
415 edifices such as those found underneath VC6. The second phase saw the explosive submarine
416 eruptions forming most of the cones of the KVC, in addition to the effusive formation of VC16,
417 which lies off the main trend of the KVC.

418 5.2 The role of tectonics

419 The Kolumbo Chain forms two main trends that lie parallel to the NE-SW striking direction of the
420 basin bounding faults of the Santorini-Amorgos Tectonic Zone (e.g. Nomikou et al., 2018).
421 Hübcher et al. (2015) related these two trends with two faults that occur in the eastern Anhydros

422 Basin. According to our study, the eastern fault trend is linked to an internal fault zone in the
423 Anhydros Basin, while the western fault trend is connected to the Ios Fault in the Anhydros Basin,
424 implying a direct tectonic control of the KVC. In contrast, a recent study based on seismic
425 anisotropy along the Anhydros Basin concluded that magmatism is not localized in areas of higher
426 fault density, but influenced by the regional-scale tectonic regime (Heath et al., 2021).

427 The seismic profiles shown in Figure 5 indicate that two prominent faults extend the two trends of
428 the KVC towards the northeast into the eastern Anhydros Basin. Fault Ab2 shows a significant
429 throw, offsetting the basement reflection by up to 150 m (Fig. 5a-c). This fault can be clearly
430 identified directly underneath VC20, as visible in Figure 5c, and seems to continue the strike of
431 the southeastern trend of the KVC far into the Anhydros Basin, where it is expressed as a complex
432 system of intra-basin faults (Fig. 5e), in agreement with Hübscher et al. (2015). Fault Ab3 seems
433 to continue the strike of the northwestern trend of the KVC and seems to continue underneath the
434 volcanic cones VC17 and VC18 (Fig. 5a, b). However, due to the acoustic disturbances underneath
435 the other cones, we cannot reliably trace faults Ab2 and Ab3 further underneath the KVC. On the
436 other hand, the spatial trend of these faults (Fig. 5f) strongly indicates that these faults had an
437 important influence on the volcanic plumbing system of the KVC, with volcanoes evolving both
438 above and in between these faults (Fig. 5). Onlap terminations of the volcanic cones do not indicate
439 that one of the two trends is younger than the other, since, as can be seen in Figure 7b, there are
440 onlap terminations between individual cones of both trends, indicating that no clear spatial age
441 trend can be derived. Thus, the formation of the KVC appears to have occurred as a phase of
442 widespread volcanism along both trends of the KVC (Fig. 7b).

443 Figure 5 also indicates that the throw of faults Ab2 and Ab3 decreases towards Unit 6, indicating
444 that the main active phase of these faults was the time when Units 3-5 were deposited. This is
445 particularly evident in Figure 5d, where Units 4 and 5 show significant divergence towards Fault
446 Ab2. This is consistent with the temporal concept presented in Figure 7a, which indicates that the
447 KVC was formed during the deposition of Units 3 and 5. Thus, in addition to the spatial aspect,
448 this also suggests a temporal volcano-tectonic control of the KVC, i.e. that the timing of faulting
449 corresponds to the evolution of the cones along the KVC.

450 5.3 Link between the Kolumbo Volcanic Chain and the plumbing system of Santorini

451 Our analysis has shown that the spatio-temporal evolution of the KVC is complex, including both
452 explosive and effusive volcanism over long timescales. This raises the question of how these
453 different phases are related to the volcanic plumbing system of Santorini. While the overprint of
454 the thick Thera Pyroclastic Formation and several caldera collapse events complicate the analysis
455 of the early evolution of Santorini, our seismic data allow the region between Santorini and
456 Kolumbo to be imaged, where the Kolumbo Ridge connects the northeastern flank of Santorini
457 with Kolumbo (Fig. 1c).

458 The seismic profiles in Figures 6b and 6c illuminate the internal architecture of the Kolumbo
459 Ridge, revealing a zone of acoustic blanking with some scattered high-amplitude reflections
460 beneath, indicating the presence of stacked volcanic edifices or widespread intrusions. The
461 location of the Kolumbo Ridge is consistent with the low-velocity zone from McVey et al. (2020)
462 that extends from Santorini to Kolumbo at 3.5 km depth, which they interpreted as a zone of
463 extensive magmatic intrusions. Figure 8a shows the spatial extent of the zone of acoustic blanking

464 underneath the Kolumbo Ridge and the KVC, which has a similar orientation to the deep low-
465 velocity zone of McVey et al. (2020), and its boundaries coincide with the trend of the Kameni
466 and Kolumbo Lines (Fig. 8a). Although we cannot trace faults Ab2 and Ab3 underneath the KVC
467 and the Kolumbo Ridge, their orientation also broadly matches the trend of the Kameni and
468 Kolumbo Lines (Heath et al., 2019) suggesting a major volcano-tectonic zone connecting
469 Santorini, the Kolumbo ridge, and the KVC. Onshore geological mapping shows the existence of
470 several NE-SW striking faults as well as numerous dykes on the northeastern flank of Santorini,
471 which could represent the shallowest expression of this large-scale fault zone (e.g., Druitt et al.,
472 1999; Drymoni et al., 2022).

473 In addition to the Kolumbo Ridge, our seismic data also reveal several smaller volcanic edifices
474 in the area between Santorini and Kolumbo. The seismic profile in Fig. 4a shows that the cone
475 forming Kolumbo's Unit K3 had a separate vent located several kilometers southwest of the
476 present-day crater (area of strong acoustic blanking in Fig. 6a). We also detect some smaller
477 volcanic features in the area between Santorini and Kolumbo, such as the Oia Cone (Fig. 4a) or
478 smaller zones of acoustic blanking, which may be related to shallow intrusions or smaller
479 extrusions (Figs. 2a, 4b, 8). This shows that the area between Santorini and Kolumbo has been
480 volcanically active in the past. Considering that volcanic edifices from Phases 2 and 3 have also
481 been identified southwest of Santorini, such as the Poseidon center and the Aspronisi cones (Preine
482 et al., 2022a), this shows that volcanism in the CSK field was much more widespread in previous
483 phases (Fig. 8a). This is supported by recent findings of Pank et al. (2022), who sampled submarine
484 lava outcrops in the Santorini caldera and found several samples with ages of ~ 255 ka and $\sim 309 \pm$
485 30 ka (for location, see Pank et al., (2022) and Fig. 8a). These samples fill an age gap in the
486 volcanic history of Santorini, as the transition between Peristeria volcanism (550-450 ka) and the
487 onset of the first eruptive cycle is not well constrained (Pank et al., 2022). These authors further
488 show that these samples have a similar Sr-N-Pb isotopic composition to the Peristeria volcano, but
489 argue that the samples belong to a previously unknown stage of Santorini volcanism. Considering
490 the low accuracy of absolute age estimates from seismic stratigraphy, the boundary between phases
491 3 and 4 (~ 360 ka) as defined in Preine et al. (2022a) has a considerable error margin. So far, the
492 age model is based on the sedimentation rate extrapolations and the correlation to the onset of the
493 first eruptive cycle on Santorini, which is based on tentative ages for Cape Therma 1 and Cape
494 Therma 2 from Vakhrameeva et al. (2018, 2019) (Pank et al., 2022). Thus, it is plausible that the
495 lavas of Pank et al. (2022) belong to Phase 3 and thus correspond to the continuation of the
496 widespread volcanism of phase 3, which was subsequently masked by the TPF volcanism and
497 multiple caldera collapses.

498 Our reconstruction of the spatio-temporal evolution of the KVC in the context of the entire CSK
499 volcanic field and the surrounding tectonic system is illustrated in Figure 8b-e. According to this
500 model, after volcanism initiated in Late Pliocene/Early Pleistocene with the emergence of the large
501 Christiana edifice (Phase 1, Fig. 8b), it became widespread in the Middle Pleistocene, forming
502 volcanic centers southwest and northeast of present-day Santorini including the first episode of the
503 KVC (Phase 2, Fig. 8c). During this period, the tectonic system started to form prominent NE-SW
504 striking faults, including faults Ab2 and Ab3, which appear to have strongly influenced the
505 emplacement of volcanic edifices during this phase (Fig. 8d). After a regional tectonic pulse
506 affected the entire CSK rift system and a major mass-wasting cascade occurred at proto-Santorini
507 (Preine et al., 2022b), another episode of wide-spread volcanism took place, which included the
508 onshore exposed Akrotiri and Peristeria centers, the Aspronisi cones SW of Santorini, the newly-

509 discovered Oia Cone between Kolumbo and Santorini, as well as large parts of the younger KVC
510 (Fig. 8d). This widespread volcanism, which occurred along a large SW-NE oriented region,
511 suggests that the volcanic plumbing system of the different edifices was laterally connected over
512 a wide area, for example through long dykes systems that are typical for lateral connections along
513 rift systems (e.g. Bato et al., 2018).

514 The transition from Phase 3 to Phase 4 is marked by another major rifting event, which affected
515 predominantly the northeastern Santorini-Anafi Basin (Fig. 1b) (Preine et al., 2022c). This tectonic
516 event had a major influence on the volcanic plumbing system of the KVC since, afterward,
517 volcanism became more spatially isolated and explosive, focusing mainly on the northern caldera
518 basin of Santorini (forming the TPF) and Kolumbo, which had two major eruptions including the
519 1650 CE K5 eruption (Preine et al., 2022c). This tectonic pulse also corresponds to a change in
520 melt diversity of the eruptive products of Santorini (Flaherty et al., 2022). We argue that the large-
521 scale tectonic event marking the transition from Phase 3 to Phase 4 might have interrupted the
522 connection of the volcanic systems of Santorini and Kolumbo, which seem to have been connected
523 during Phase 3. This could have led to a focusing of volcanic activity on distinct centers during
524 Phase 4. This would explain why there is geophysical evidence for both a deep (McVey et al.,
525 2020) and a shallow (this study) connection between Santorini and the KVC from previous phases,
526 while geochemical analyses of the eruptive products show clear differences between the two
527 systems (Klaver et al., 2016; Rizzo et al., 2016).

528

529 **6 Conclusions**

530 In this study, we have used reflection seismic profiles to reconstruct the spatio-temporal evolution
531 of the Kolumbo Volcanic Chain (KVC) and its relationship to the Santorini volcanic system. We
532 show that the KVC evolved in two main episodes. The first episode occurred at approximately 1
533 Ma and formed volcanic edifices along a broad NE-SW trending zone northeast of Santorini. While
534 most cones of the volcanic edifices of this episode are buried, some have only a thin sedimentary
535 cover or are exposed at the seafloor. These cones seem to have been formed mainly by effusive
536 eruptions, forming thick layers of acoustic blanking in the seismic data. In contrast, volcanoes of
537 the second episode were formed mainly during submarine explosive eruptions between about 0.7
538 and 0.3 Ma and formed well-stratified pumice cones that generally cause only minimal acoustic
539 disturbances below, although at least one of these younger cones also likely formed during effusive
540 eruptions.

541 We show that the two main trends of the KVC correspond to two faults that continue towards the
542 eastern Anhydros Basin. Most of the cones formed either on top of or between these faults,
543 indicating a pronounced influence of local tectonism on the volcanic evolution of the KVC. We
544 also identify several buried volcanic centers in the area between Santorini and Kolumbo, as well
545 as a broad zone of acoustic blanking connecting Kolumbo with the northeastern flank of Santorini,
546 which we interpret as a zone of widespread volcanic intrusions. This suggests that volcanism was
547 much more widespread in the early evolution of Santorini, and occurred along a broad NE-SW
548 trending zone that probably continued further beneath present-day Santorini. At some point, a

549 major tectonic event disconnected these systems, explaining the distinct geochemical signatures
550 of the recent eruptive products of Kolumbo and Santorini.

551 Our study highlights that high-resolution seismic imaging is a versatile tool for studying submarine
552 volcanoes that are difficult to access otherwise. We show that seismic imaging can reveal buried
553 volcanic structures, which would otherwise remain unrecognized, and allows the evolution of
554 volcanic plumbing systems in space and time to be reconstructed. Similar high-resolution seismic
555 surveys at the neighboring volcanic centers of the Hellenic Arc would provide a much clearer
556 picture of the volcanic evolution and tectonic controls of this back-arc system, which is important
557 for a more reliable hazard assessment of the region.

558 **Data availability statement:**

559
560 SEG-Y files of the seismic lines shown in Figure 2-6 are submitted to the Marine Geoscience Data
561 System and will be publically accessible soon. Link and data DOI will be updated during the
562 revision process.

563

564 **Acknowledgments**

565 We would like to thank the captains, crews, and scientific parties of RV Poseidon POS338 and RV
566 Aegeo THERA expeditions. We thankfully acknowledge the support of the German Research
567 Foundation DFG (HU690/25-1). In addition, we are grateful to Schlumberger for providing
568 VISTA seismic processing software and IHS Markit for providing KINGDOM seismic
569 interpretation software.

780 **Figure captions**

781 **Figure 1:** (a) Regional map of the southern Aegean Sea showing the Hellenic Volcanic
 782 Arc (shaded red) with volcanic centers marked by red triangles. The coordinate system
 783 here (and in subsequent maps) is UTM Zone 35N, WGS84 datum. The red box indicates
 784 the study area shown in (b). (b) Morphological map of the CSK rift zone showing islands,
 785 basins, volcanic centers, and major extensional structures (red lines), after Nomikou et al.
 786 (2016b, 2018, 2019) and Preine et al. (2022b). Grey lines indicate all available seismic
 787 profiles. KaL: Kameni Line; KoL: Kolumbo Line (after Heath et al., 2019). Bathymetry
 788 from Nomikou et al. (2012, 2013, 2018, 2019) and Hooft et al. (2017). (c) Close-up of the
 789 western Anhydros Basin showing the KVC and major structural elements. Color scale same
 790 as (b). (d) Profile curvature from the bathymetric map shown in c. Volcanic cones are
 791 labeled according to Nomikou et al. (2012) and Hooft et al. (2017). Asterisks indicate cones
 792 with summit craters. A northeast-trending ridge identified in this study is labeled
 793 “Kolumbo Ridge”. Orange lines indicate the two main trends of the KVC (Nomikou et al.,
 794 2012).

795
 796 **Figure 2:** (a) NW-SE oriented seismic profile HH06-22 crossing the Anhydros Basin and
 797 Kolumbo. KF: Kolumbo Fault. (b) SW-NE oriented seismic profile UHH06-35 crossing
 798 Kolumbo and several cones of the KVC. Orange triangles mark onlap terminations.
 799 Colored horizons h1-h6 mark key reflections separating seismostratigraphic units U1-U6
 800 from Preine et al. (2022a). K1-K5: Kolumbo Units after Hübscher et al. (2015). VC:
 801 volcanic cone. KF: Kolumbo Fault. Inset map is an extract from Figure 1c, showing the
 802 locations of the profiles in (a) and (b). See Figure S2 for an uninterpreted version of the
 803 seismic profiles.

804
 805 **Figure 3:** (a) Seismic profile UHH06-24 crossing the Anhydros Basin and the
 806 southwestern part of the KVC. (b) Seismic profile UHH06-25 crossing the Anhydros Basin
 807 and the central part of the KVC. (c) Seismic profile UHH06-02 across the Ios shelf, the
 808 Anhydros Basin, and the central part of the KVC. Inset map is an extract from Figure 1c,
 809 showing the locations of the profiles in (a) - (c). See Figure S3 for an uninterpreted version
 810 of the seismic profiles.

811 **Figure 4:** (a-f) Detailed illustration of the internal architecture of several cones of the KVC.
 812 Left panels show seismic amplitude and right panels show instantaneous phase. SF1, SF2:
 813 Seismic facies as explained in the text; HAR: High-Amplitude reflection. See Figure S4
 814 for an uninterpreted version of the seismic profiles.

815 **Figure 5:** Seismic profiles across the northeastern KVC and the eastern Anhydros Basin
 816 (a-e). Profiles in (b) and (c) are single-channel seismic profiles, in which the yellow arrows
 817 indicate the position of the bubble reflection (acquisition artefact). Prominent faults Ab1-
 818 Ab3 are highlighted and their location is indicated in the map (f). IF: Ios Fault; AhF:
 819 Anhydros Fault. See Figure S5 for an uninterpreted version of the seismic profiles.

820 **Figure 6:** (a) Seismic profile UHH06-29 traversing the northeast flank of Santorini,
 821 Kolumbo, and the Anhydros Horst. (b) Seismic profile UHH06-19 crossing the Anhydros

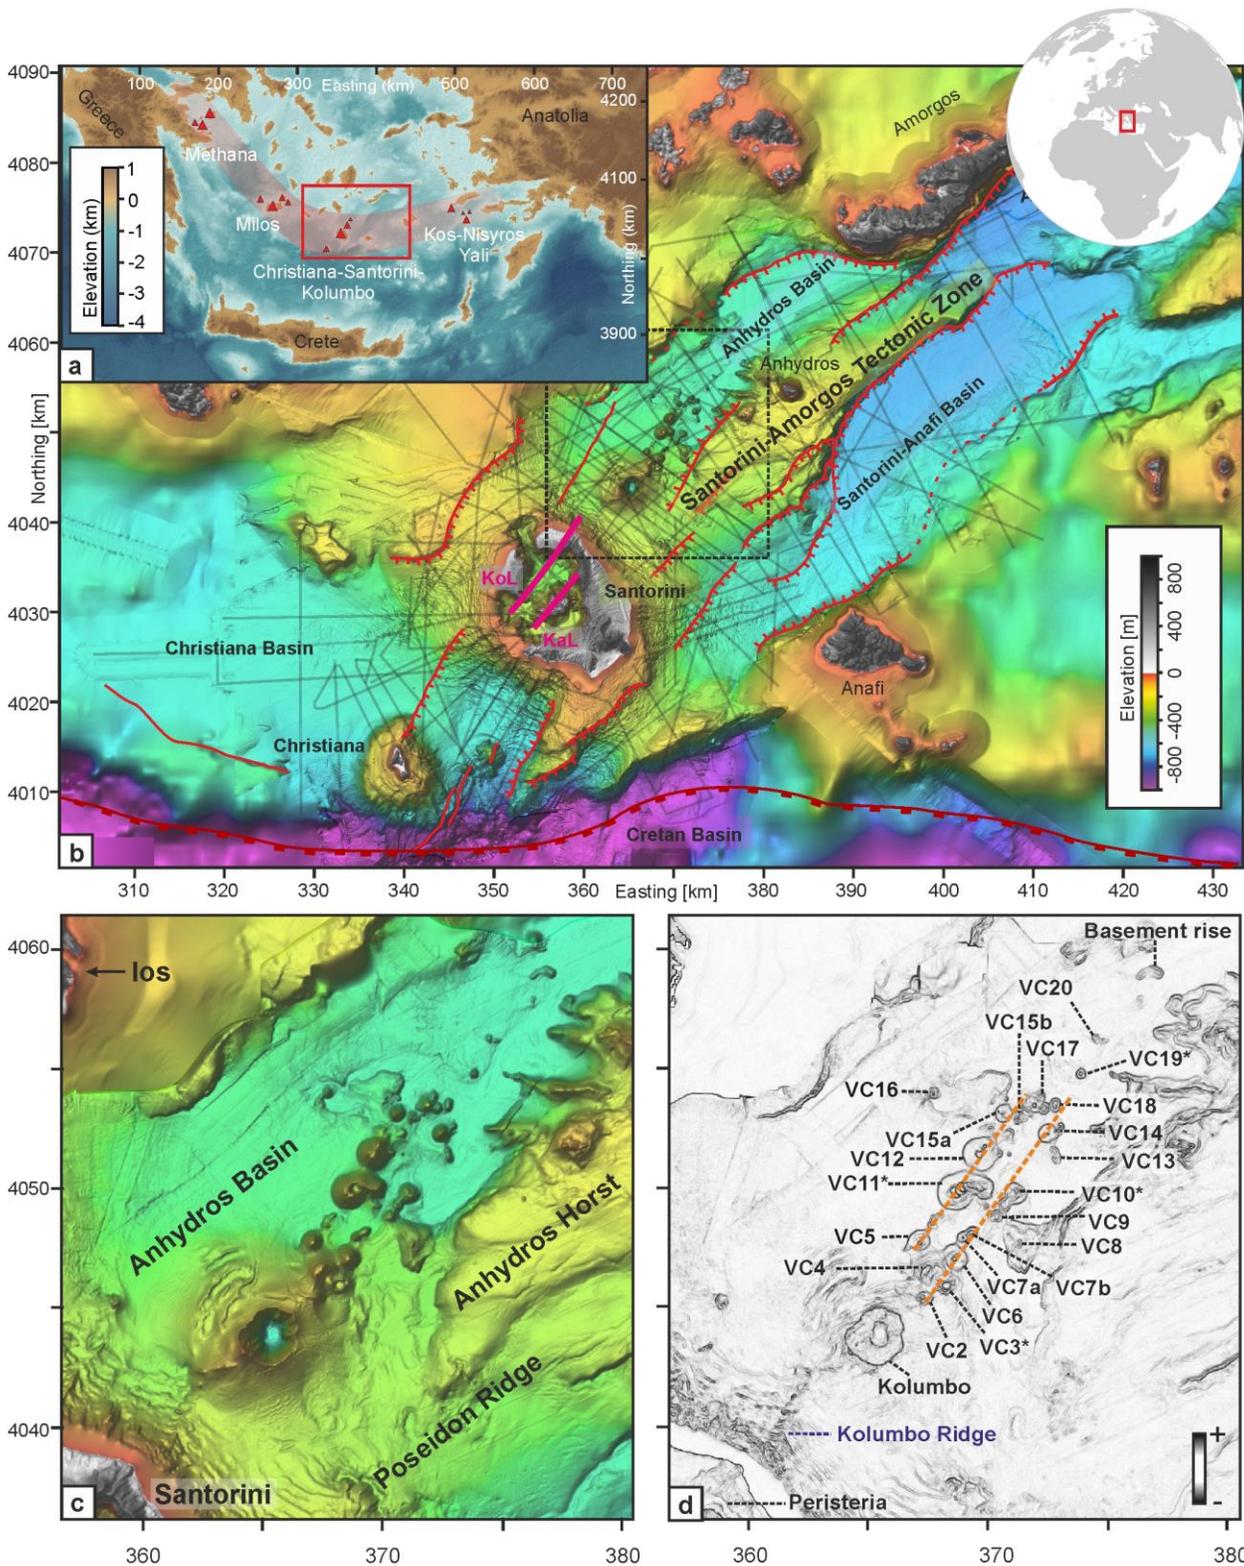

822 Basin and the Kolumbo Ridge between Santorini and Kolumbo. (c) Seismic profile
823 UHH06-38 crossing the northeastern flank of Santorini. Inset map show the locations of
824 the seismic lines in (a)-(c). See Figure S6 for an uninterpreted version of the seismic
825 profiles.

826 **Figure 7:** (a) Relative timeline of the evolution of the CSK volcanic field, placed in the
827 context of the chronostratigraphic framework of Preine et al. (2022a) – i.e. horizons h3 –
828 h6. Ch.: Christiana, TPF: Thera Pyroclastic Formation, LBA: Late Bronze Age eruption,
829 VC = volcanic cone, OC = Oia Cone. Black arrows indicate increasing age from one
830 volcanic cone to the next. (b) Map of profile curvature showing the direction of onlap
831 terminations from individual cones inferred from the seismic lines. (c) Schematic diagram
832 showing the interpreted internal architecture of exemplary volcanic edifices of the KVC.
833 The approximate location of the sketched section is indicated by the dashed black line in
834 (b). SF: Seismic facies, HAR: High-Amplitude reflection.

835 **Figure 8:** (a) Morphological map of the CSK rift zone showing major volcano-tectonic
836 features before the onset of the Thera Pyroclastic Formation (TPF, ~0.3 Ma). Outline of
837 proto-Anhydros Basin taken from Heath et al. (2019) and Preine et al. (2022c). Previously
838 identified faults from Nomikou et al. (2019) and Preine et al. (2022c). Kameni and
839 Kolumbo Lines according to Heath et al. (2019). Low-Velocity Volume zone from McVey
840 et al. (2019). Locations of cones from Phases 1-3 taken from Preine et al. (2022a) and from
841 this study. Locations of sampled lava outcrops from Pank et al. (2022). (c-e) Sketches of
842 the spatio-temporal evolution of the Kolumbo Volcanic Cones (KVC) in the context of the
843 entire Christiana-Santorini-Kolumbo volcanic field (according to Preine et al., 2022a). Red
844 semi-transparent color indicates the approximate area of volcanic activity during each
845 phase. Fault evolution according to Preine et al. (2022c). Present-day coastlines for spatial
846 reference.
