10 **Key Points:**

11 - A new generalized strategy for obtaining the lithospheric thickness from S-wave receiver
12   functions (GC_SRF) is proposed.

13 - This GC_SRF strategy can rebuild the Sp converted phase from either full wavefield
14   synthetic seismograms or field data without artificats.

15 - Lateral variations in the lithospheric structure from the Sichuan Basin to Tengchong
16   Volcano in southeastern Tibet are investigated.

17

18 **Abstract**

19 The selected rotation angle and deconvolution time window during S-wave receiver function
20 (SRF) calculations and the final SRF quality control may introduce artificial interference. Here
21 we overcome these problems by proposing a new strategy, the GC_SRF strategy, which employs
22 grid search and correlation analysis to obtain reliable SRFs. Extensive tests using synthetic and
23 real data suggest that the GC_SRF strategy is a suitable approach for constraining lithospheric
24 thickness, and reproducible and robust depth estimations of the lithosphere–asthenosphere
25 boundary (LAB) are obtained. Specifically, this GC_SRF strategy can restore the weak Sp
26 phases from full wavefield synthetic seismograms. Similar, but clearer, discontinuity patterns
27 that contain no artificial interference compared with those obtained in previous studies of
28 southeastern Tibet are produced here. The post-stack migrated SRFs reveal that the Chuandian
29 region has a thicker crust and either a poorly defined or unclear LAB, whereas a thinner crust
30 and clear LAB is present at ~160 km depth beneath the Sichuan Basin. The absence of a
31 continuous LAB in the Chuandian region may suggest lithospheric regrowth due to mantle
32 plume processes.

33 **Plain Language Summary**

34 As the outermost shell of the solid Earth, the lithosphere attracts great attention because it can be
35 considered a natural "archive" that records the evolutionary history of the Earth. In addition, it
36 represents the Earth's reservoir for mineral resources, and oil, and gas, and it is the origin of
37 numerous natural disasters, such as volcanic eruptions and earthquakes. It is therefore essential
38 to understand the spatial morphology of the lithosphere and its evolution. In this study, we
39 introduce a new strategy, the GC_SRF strategy, to obtain the lithospheric thickness while
40 avoiding any potential artificial interference based on the traditional S-wave receiver function
41 technique. This newly developed strategy can obtain robust and clear lithospheric thicknesses
42 from synthetic seismograms. We also analyze real data to image the lithospheric structure in
43 southeastern Tibet based on this GC_SRF strategy, which provides consistent but clearer results
44 compared with previous studies. This strategy can be applied to other complex geological
45 environments to advance our understanding of geodynamic processes.

1. Introduction

The lithosphere–asthenosphere boundary (LAB) is generally considered to be a negative velocity gradient transition zone from the cold and fast lithosphere to the warm and slow asthenosphere. Its depth varies considerably, ranging from <50 km beneath the youngest ocean to >200 km beneath cratonic regions (Thybo, 2006; Fischer et al., 2010; Hopper & Fischer, 2015; Fischer et al., 2020). The precise positioning of the LAB provides good constraints on the evolution of cratons and orogens, such as lithospheric thinning owing to extension (Buck, 1991) and lithospheric thickening owing to collision (Houseman et al., 1981). A series of methods, such as receiver functions (P- and S-wave receiver functions; PRFs and SRFs, respectively), SS precursors, and body-wave and surface-wave tomography, have been developed to detect the lithospheric thickness at both global (Bijwaard & Spakman, 2000; Ritzwoller et al., 2002; Ritsema et al., 2004) and local scales (Rawlinson & Fishwick, 2012; Mojaver et al., 2021; Zhang et al., 2021).

SRFs are the most widely used method for detecting the LAB because the Sp converted phase is remarkably sensitive to the vertical velocity gradient across the LAB (Chen et al., 2009; Hansen et al., 2010; Hu et al., 2011; Zhang et al., 2014; Liu et al., 2021; Liu & Zhao, 2021; Thybo et al., 2021). Coordinate system rotation and deconvolution are important steps for obtaining SRFs. However, the incident angle of the planar S wave could be different from the synthetic value due to the complexity of the earthquake mechanisms and near-surface structures beneath the seismic stations. The deconvolution time window may also include mixtures of different seismic phases. Here, we identified the incidence angle (Inci_Ang) and window length (Win_Len) as the two key parameters in this study. We calculated the SRFs by varying these two parameters to mimic the three-component waveforms at station ST09 on the Tibetan Plateau, which has been analyzed in a previous study (Kumar et al., 2006). Figure 1 shows that different values of these two parameters can indeed affect the shape of the SRFs. The waveform amplitude at time zero could be either negative or positive for different Inci_Ang and Win_Len values. Furthermore, the quality control process of the estimated SRFs could also influence the stacking and migration results. Therefore, the inappropriate selection of the coordinate rotation angle and deconvolution time window, and following quality control process would potentially bias the resultant LAB depth.
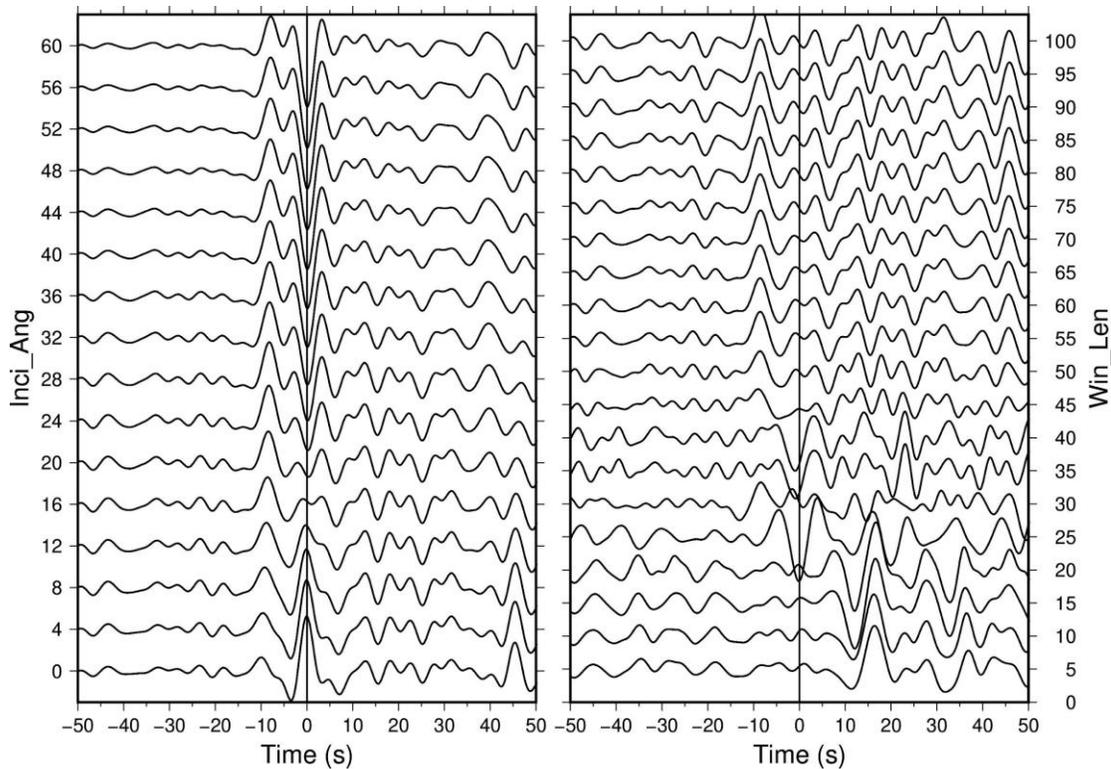

Figure 1. The influence of the incidence angle (Inci_Ang) and deconvolution time window length (Win_Len) on the shape of the S wave receiver function.

Various efforts have been made to optimize the coordinate rotation angle and quality control process to improve the reliability and stability of the constructed SRFs. Minimizing the amplitude at time zero (Kumar et al., 2006; Yuan et al., 2006; Kind et al., 2012; Zhang et al., 2012), measuring the polarization angle based on the S-wave particle motion (Farra & Vinnik, 2000; Vinnik et al., 2004), and converting from the apparent velocity (Reading et al., 2003; Hu et al., 2011) are all reliable approaches for determining the possible rotation angle. The quality control process includes visual inspection, signal-to-noise ratio (SNR) constraints (Hansen et al., 2010; Shen et al., 2019), and bootstrap estimation (Hansen et al., 2009; Xu et al., 2017; Xu et al., 2019). However, these methods could introduce artifacts based on the parameters chosen. A robust and repeatable strategy that avoids artificial interference when obtaining SRFs has not been implemented to date.

Here we focus on avoiding such artificial interference when obtaining the lithospheric thickness by varying Inci_Ang and Win_Len during the SRF calculation and then performing a quality control on the resultant SRFs. We develop the GC_SRF strategy to extract stable SRFs

93   and guarantee reproducibility, where the "G" and "C" represent the grid search and correlation

94   analysis, respectively. Specifically, we first perform a grid search to obtain the two parameters,

95   Inci_Ang and Win_Len. We then analyze the SRFs corresponding to different combinations of

96   these two parameters via cross-correlation to obtain the optimal SRF. The root mean square error

97   (RMSE) algorithm is introduced to perform the quality control process in real data cases. Parallel

98   computing is introduced to ensure computational efficiency of the GC_SRF strategy. This

99   strategy has been effectively applied to both full wavefield synthetic seismograms and real data

100   sets collected in southeastern Tibet.

101   **2. Method**

102   The GC_SRF strategy is schematically illustrated in Figure 2. This approach contains

103   coordinate rotation and discrete deconvolution (Farra & Vinnik, 2000; Wilson et al., 2006; Yuan

104   et al., 2006) steps during the SRF calculation process. We follow the approach outlined in Kumar

105   et al. (2006) and Yuan et al. (2006) to rotate the raw data from the ZNE system to the LQT

106   system and determine the optimal Inci_Ang value by minimizing the amplitude at time zero on

107   the L component.
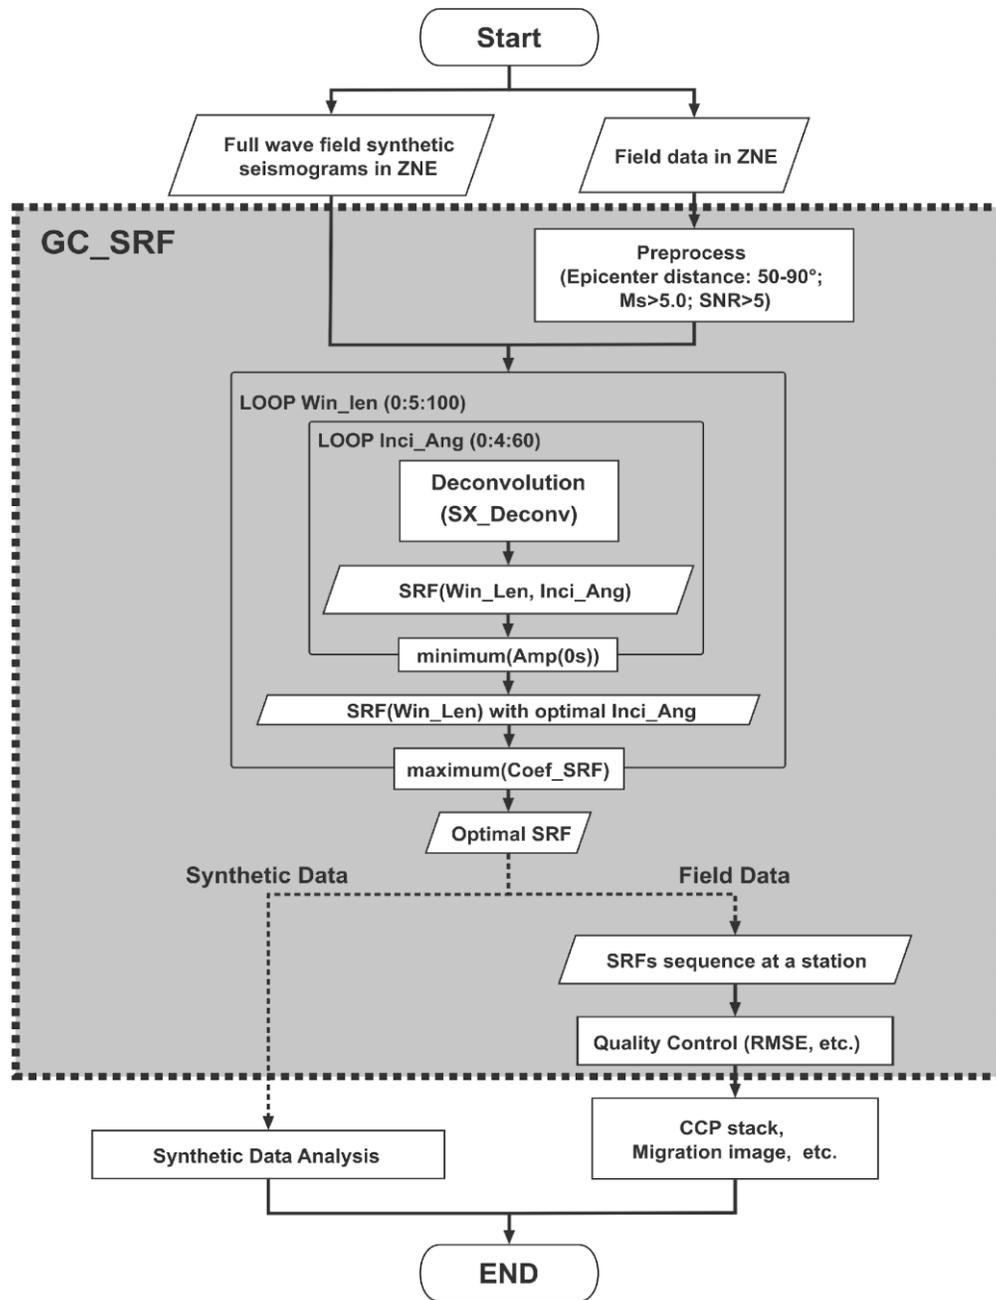

Figure 2: Flow chart of the GC_SRF strategy.

110   The concept of discrete deconvolution has been employed in reflection seismology since

111 the 1950s (Robinson & Treitel, 2000), and it was later introduced in passive seismology, where it

112 has since been developed into different algorithms, such as time-domain iterative deconvolution

113 (Ligorria & Ammon, 1999), wiener filter deconvolution (Wu et al., 2003a), water level

114 deconvolution (Langston, 1979), maximum entropy spectrum deconvolution (Wu et al., 2003b),

115   homomorphic deconvolution (Oppenheim, 1969; Ulrych et al., 1972), and spiking deconvolution

116   (Treitel & Robinson, 1966; Robinson & Treitel, 1976; 2000). We have chosen spiking

117   deconvolution in the GC_SRF strategy because of its wide use and efficiency in previous SRF

118   studies (Farra & Vinnik, 2000; Yuan et al., 2006; Kind et al., 2012). Spiking deconvolution is

119   employed in the LQT coordinate system to estimate an inverse filter based on a chosen time

120   window of the Q-component waveform (Levinson, 1946; Rost & Thomas, 2002). The length of

121   the time window (Win_Len) led directly to the instability of the deconvolution results (see

122   Figure 1).

123   The spiking deconvolution algorithm that is used in most studies is enclosed in the

124   Seismic Handler (Stammler, 1993), which is now inconvenient to use because it has not been

125   maintained for nearly a decade. We therefore reconstruct the spiking deconvolution algorithm as

126   a binary executable named SX_Deconv using the C++ compiler to handle and transplant the

127   algorithm for different applications. We reproduce the results presented in Kumar et al. (2006) to

128   validate the effectiveness of SX_Deconv. Figure 3 provides a comparison of the SRFs obtained

129   by two algorithms for a Ms 6.4 earthquake event in 1998 at station ST09, with the Kumar et al.

130   (2006) result shown in Figure 3a and the SX_Deconv result, where Inci_Ang varies from 0 to 60

131   and Win_Len is set to 85, as shown in Figure 3b.
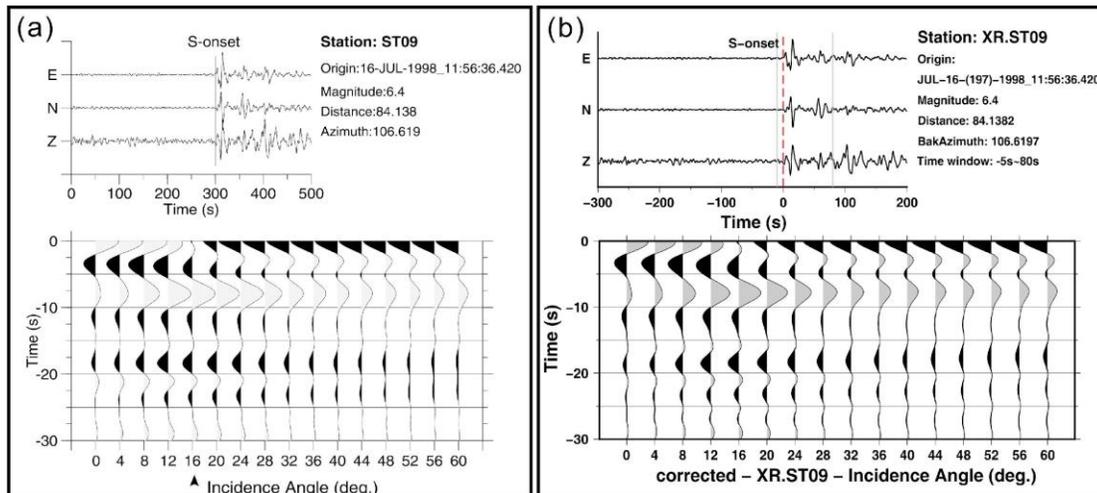

132

133   **Figure 3:** SRFs at station ST09 in southwestern Tibet with an Ms 6.4 earthquake event in 1998.

134   (a) An example edited from Figure 4b in Kumar et al 2006. (b) Result using SX_Deconv. The

135   top panel represents the original three-component event waveforms and event information. The

136   bottom panel shows the SRFs corresponding to different incidence angles with deconvolution

137   time window length fixed to 85 s.

138   The upper panel in Figure 3 shows the original seismic event waveform and earthquake

139   information, which indicates that the event waveform we collected from the Incorporated

140   Research Institutions for Seismology (IRIS) is the same as that in Kumar et al. (2006). The lower

141   panel of Figure 3 shows the calculated SRFs for different rotation angles, with identical SRFs on

142   both sides that possess clear Sp phases, a positive Smp phase near –8 s, and a negative SLp phase

143   near –18 s. These results validate the application of this algorithm to obtain SRFs from both

144   synthetic and real data.

145   The three-component event waveforms that were recorded in the ZNE coordination

146   system serve as the inputs for the GC_SRF strategy. We prepare the input data for the synthetic

147   cases via the following procedure: (1) apply a 50- to 4-s bandpass filter; (2) clip the waveforms

148   from 200 s before to 200 s after the theoretical S-wave arrival time, which was calculated using

149   the IASP91 model (Kennett & Engdahl, 1991) and TauP Toolkit (Crotwell et al., 1999); and (3)

150   detrend, demean, and resample the waveforms to 0.1 s. Similarly, the preparation steps for real

151   data are: (1) select the teleseismic S waveforms for Ms ≥5.5 earthquakes with epicentral

152   distances in the 50°–90° range that possess SNR_H greater than 5; (2) remove the instrument

153   response using a 50- to 4-s bandpass filter; (3) clip the waveforms from 200 s before to 200 s

154   after the theoretical S-wave arrival time; and (4) detrend, demean, and resample the waveforms

155   to 0.1 s. Here we define the SNR_H as:

$$SNR_H = \frac{SNR_N + SNR_E}{2}, \qquad (1)$$

156   where SNR_N is the SNR of the N component and SNR_E is the SNR of the E component,

157   with the signal window defined as 5 s before to 30 s after the S-wave arrival time and the noise

158   window defined as 60 to 30 s before the S-wave arrival time.

159   The GC_SRF strategy calculates the SRFs corresponding to different Inci_Ang and

160   Win_Len values (i.e., $SRF(Inci\_Ang, Win\_Len)$). Here, Inci_Ang is varied from 0° to 60° in 4°

161   increments (Kumar et al., 2006), and Win_Len is varied from 5 s to 100 s in 5-s increments.

162   There is only one SRF waveform for each Win_Len, with the smallest absolute amplitude

163   occurring at time zero ($SRF_{\min(Win\_Len)}$). The arithmetic mean of these SRFs is redefined as the

164   reference SRF (SRF_{ref}):

$$SRF_{ref} = \frac{1}{N} \sum SRF_{\min(Win\_Len)}, \qquad (2)$$

165   where N indicates the number of Win_Len values. The cross-correlation coefficient

166   between the SRF_{ref} and $SRF(Inci\_Ang, Win\_Len)$ is then defined as:

167       $$Coef_{SRF}(Inci\_Ang, Win\_Len) = CC[SRF_{ref}, \ SRF(Inci\_Ang, Win\_Len)], \qquad (3)$$

168   where CC indicates the cross-correlation coefficient calculation. Finally, only the SRF

169   that simultaneously satisfies (1) the smallest absolute amplitude at time zero and (2) the

170   maximum $Coef_{SRF}$ will be selected as the optimal SRF. The Inci_Ang and Win_Len values

171   corresponding to this optimal SRF can either be used as a reference waveform for quality control

172   or as input parameters that can be adapted to other deconvolution methods.

173   It is still necessary to perform quality control on the estimated SRFs from real data to

174   remove any ambient noise and aliased waveforms. The results for a single station should have

175   good consistency, as has been fully demonstrated in previous receiver function studies (Kumar et

176   al., 2006; Yuan et al., 2006), because the receiver function technique reflects the structural

177   information below the station (Rost & Thomas, 2002; Kumar et al., 2010). Therefore, the RMSE

178   is applied for the quality control step. We first calculate the RMSE between each SRF and the

179   average waveform at each station. We then reorder all of the SRFs based on their RMSEs, with

180   waveforms possessing clear and consistent Smp and SLp phases tending to be at the beginning of

181   the sequence. We can select different proportions of the SRFs based on this reordered sequence

182   to perform a linear summation. The best selection percentage can be determined by comparing

183   the amplitudes of the Smp and SLp phases of the stacked waveforms that correspond to different

184   data proportions. Here, we name this reordering method RMSE reordering and the best data

185   proportion RMSE percentage.

186   **3 Applications of the GC_SRF strategy to full wavefield synthetic seismograms**

187   3.1 Application to a one-dimensional (1-D) velocity model

188   We first test the GC_SRF strategy on full wavefield synthetic seismograms using 1-D

189   velocity models to demonstrate that this strategy can effectively calculate SRFs. Several attempts

190   have been made previously to obtain synthetic full wavefield seismograms and synthetic SRFs

191   (Yuan et al., 2006; Shen et al., 2019). Yuan et al. (2006) synthesized full wavefield seismograms

192   via the reflectivity method (QSEIS, (Wang, 1999)); however, they obtained SRFs with only

193   partial wavefield synthetic seismograms to avoid the deconvolution calculation. Although the

194   partial wavefield synthetic seismograms possessed clear Sp converted phases, the observed field

195   data consist of time series signals from the full wavefield. It is therefore necessary to rebuild the

196   Sp phases from full wavefield synthetic seismograms to ensure the robustness of our proposed

197   strategy.

198   The 1-D models that are employed in this study, which are constructed to a depth of 1000

199   km based on IASP91 (Kennett & Engdahl, 1991), are shown in Figure 4, with the crust

200   simplified to a single 40-km-thick layer. We introduce a 5% negative velocity jump at either 120

201   km (SM01), 150 km (SM02), or 180 km (SM03) depth to represent the LAB, following Yuan et

202   al. (2006). We then employ the reflectivity method (Wang, 1999) to obtain full wavefield

203   seismograms (Figure 5).
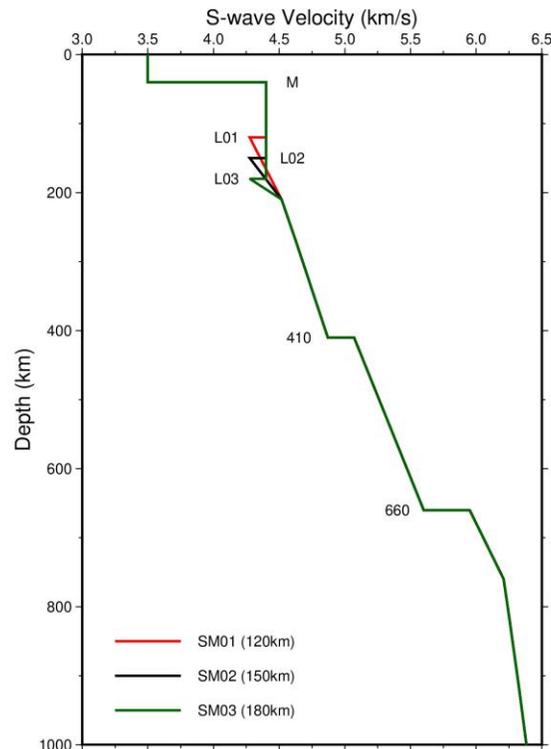

204

205   **Figure 4:** Models of S wave velocities for calculating the full wavefield synthetic seismograms.

206   Three models SM01 (red), SM02 (black) and SM03 (dark green) are plotted in different colors.

207   Compared with the IASP91 model, we simplified the crust to a single 40 km thick layer and only

208   showed the upper 1000 km of our models here.

209   The synthetic seismograms that correspond to the three models in Figure 4 are shown in

210   Figure 5. The travel time curves of the SLp phase (which represents the seismic phase converted

211   at the LAB) for the three models are plotted as dashed lines (MOD01: red, MOD02: black;

212   MOD03: green). The dashed cyan lines represent the other theoretical phases from the SM02

213   model, whose LAB depth (150 km) is between those of the other two models. It is clear that the

214   various Sp converted phases cannot be recognized easily from the full wavefield synthetic

215   seismograms. The details of the various Sp phases (including Smp, S410p, ScS410p, ScS660p,

216   SKS410p, and SKS660p) are difficult to identify on the N (Figure 5b) and Z (Figure 5a)

217   components, as these phases are significantly weaker than either the ScS or SKS phases (Figure

218   5a). This is consistent with the full wave field synthetic seismogram shown in a previous study

219   (Yuan et al., 2006), even though we use three modified velocity models in this study.
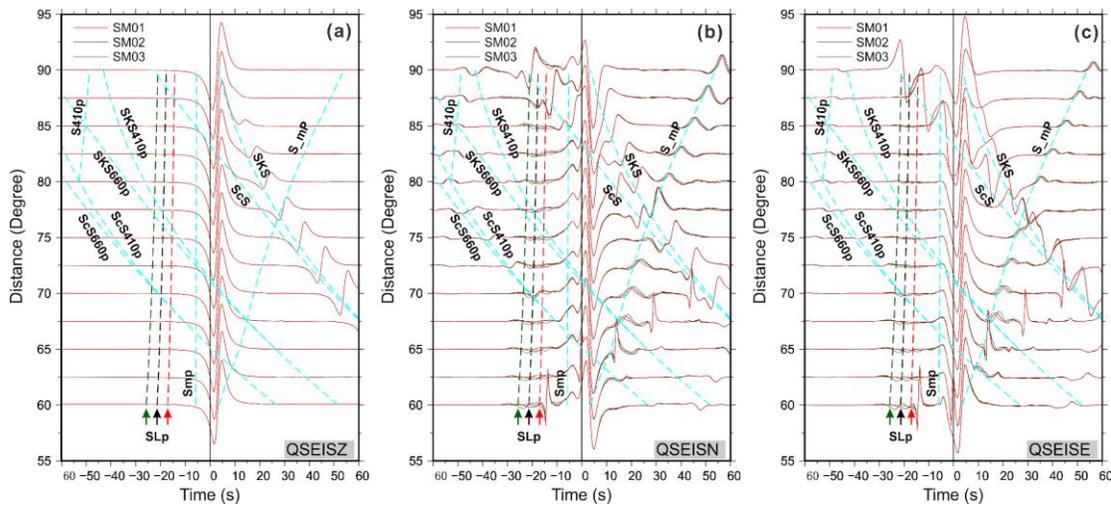

220

221   **Figure 5.** Vertical (a), North (b) and East (c) component full wavefield synthetic seismograms

222   calculated by the reflectivity method (QSEIS, Wang, 1999) for the model shown in Figure. 4.

223   Time axis is aligned by S arrival time. The main phases are labeled on the corresponding

224   components.

225   We apply the GC_SRF strategy to the full wavefield synthetic seismograms and obtain

226   SRFs for all of the Inci_Ang and Win_Len pairs. We present the GC_SRF results with an

227   epicentral distance of 75° using model SM01 in Figure 6 to compare the differences among the

228   three models (SM02: Figure S1; SM03: Figure S2). Figure 6a shows a color map of the

229   amplitudes at time zero on the L component (SRFL), whereas Figure 6b, 6g, and 6l show

230    $Coef_{SRF}$ for all of the parameter pairs. The dashed black line in Figure 6a indicates the incident

231   angles of the S phase that are calculated by the TauP Toolkit (Crotwell et al., 1999), and the

232   green crosses represent the position with the lowest amplitude; here the optimal SRF for each

233   Win_Len value is selected where there is a polarity change in the waveform. Figure 6b shows a

234   color map of $Coef_{SRF}$, with the dashed line and green crosses representing the same variables as

235   those in Figure 6a. The red crosses in these figures indicate the final optimal SRFs. The

236   waveforms of all of the SRFs in Figure 6d are shown as solid gray curves, and the waveforms

237   that correspond to the optimal SRFs for each Win_Len value are shown as solid green curves.

238   We also show the $Coef_{SRF}$ corresponding to all of the green and red waveforms in Figure 6e.

239   The red curves in Figure 6d and the red crosses in Figure 6e indicate the optimal SRF (with the

240   max $Coef_{SRF}$). Examples for models SM02 and SM03 are shown in Figures S2 and S3,

241   respectively.
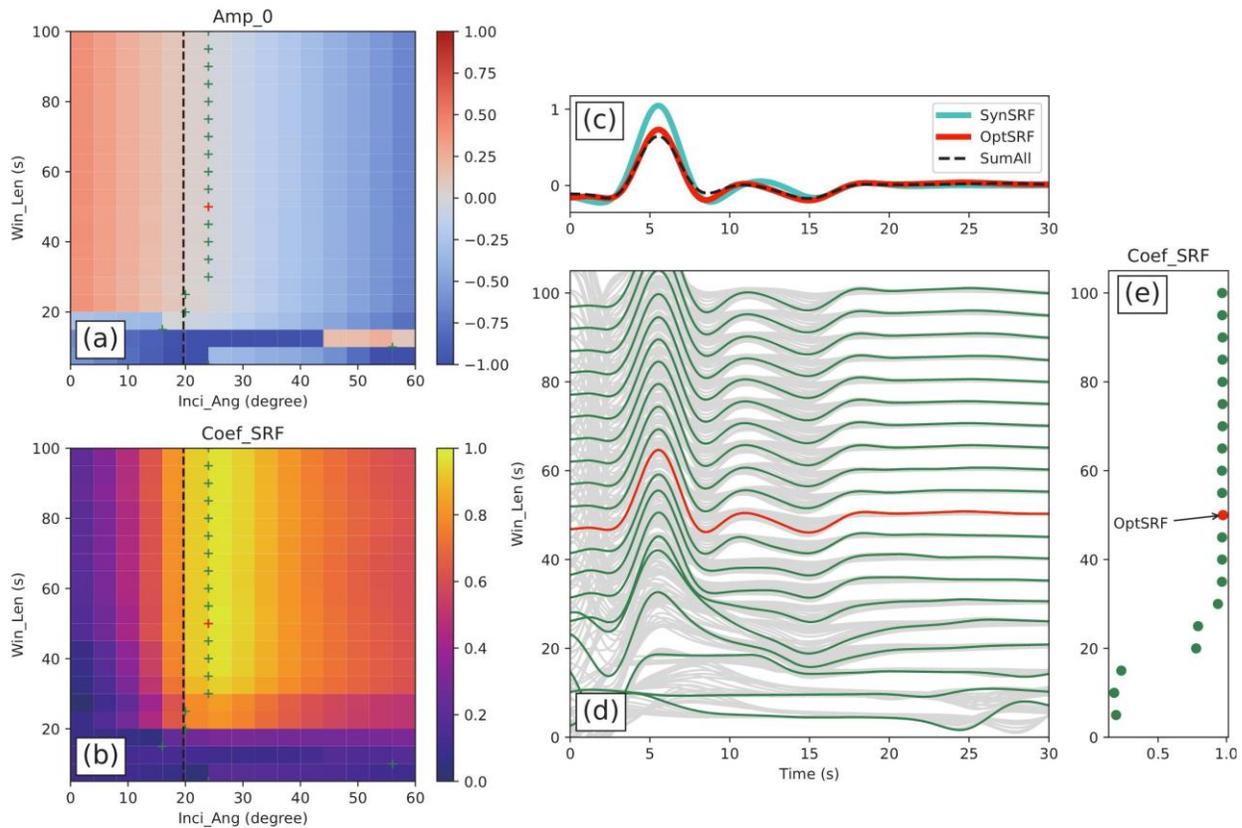

242
243   **Figure 6:** GC_SRF examples for SM01 ($t_S - t_{SLp} = 15.35s$) with an epicentral distance of 75°.

244   (a) Color map of the amplitude at time zero of the L component. (b) color map of the $Coef_{SRF}$.

245   (c) Comparison of Synthetic SRF (cyan), linear stacked SRF (black dashed), and the optimal

246   SRF from GC_SRF. (d) All the SRFs corresponding to different $Inci\_Ang$ and Win_Len pairs

247   (green curves show the optimal SRF for each Win_Len, the red curve represents the final optimal

248   SRF, and the gray curves show the other SRFs). (e) $Coef_{SRF}$ corresponding to all green and red

249   crosses in (a) and (b).

250   To present the efficiency of our proposed GC_SRF strategy, we calculate the theoretical

251   synthetic SRFs using the three models (cyan curves in Figure 6c) via the propagator matrix

252   method (Haskell, 1962). This method is efficient in obtaining the P- and SV-wave responses of a

253   horizontally isotropic layered medium, which is often compared with the observed SRF (Randall,

254   1989; Niu & Kawakatsu, 1996; Vinnik et al., 2001). The dashed black waveform in Figure 6c is

255   the linear stack of the SRFs that correspond to all the parameter pairs, whereas the red waveform

256   corresponds to the optimal SRF. The optimal SRFs are in good agreement with the theoretical

257   synthetic SRFs for the different models (Figure 6c, and Figures S1c and S2c). These tests

258   demonstrate the stability and reproducibility of the GC_SRF strategy. We then plot the optimal

259   SRFs (SRFL) as a function of epicentral distance in Figure 7a.
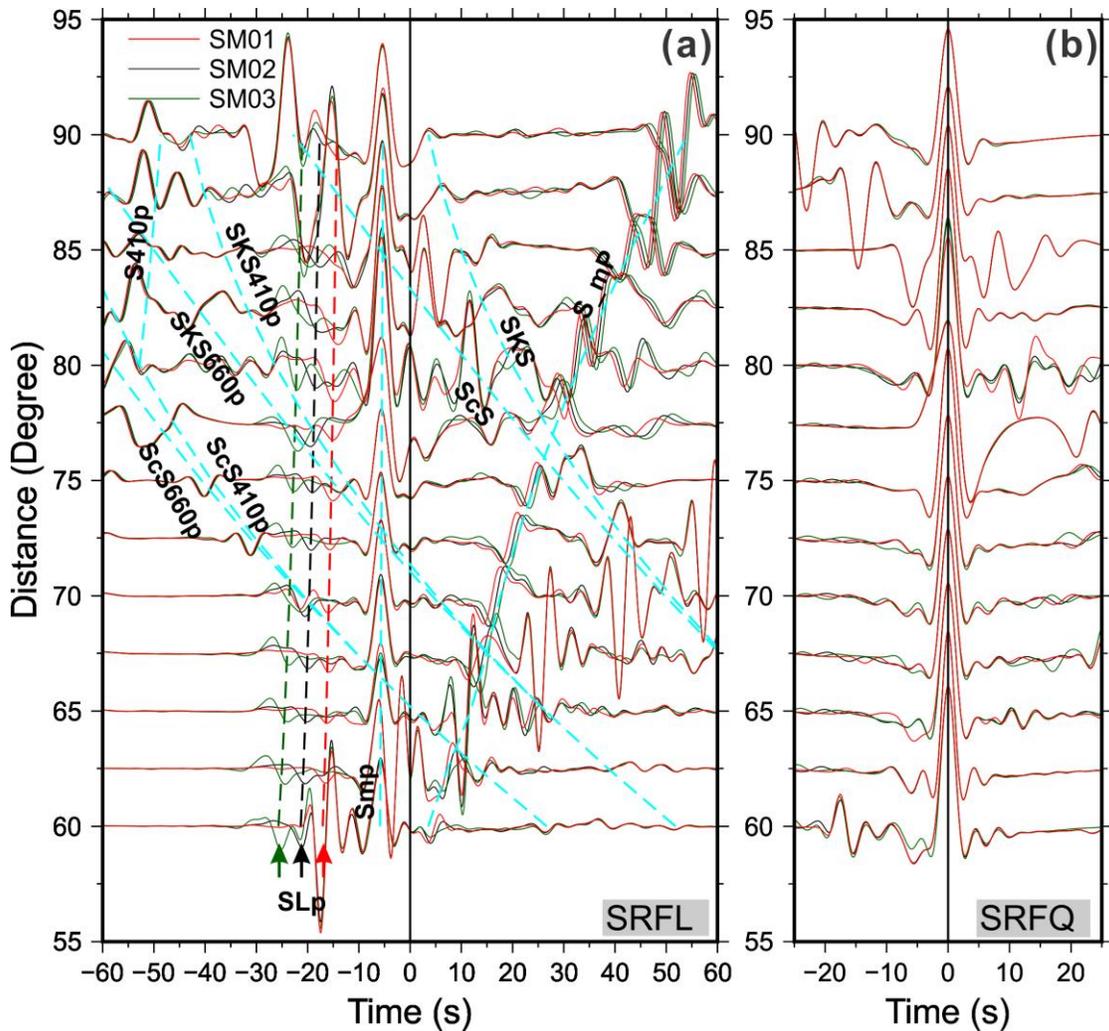

Figure 7: SRFs as a function of epicentral distances. The converted 'p' phases are labeled, including Smp, SLp, S410p, ScS410p, ScS660p, SKS410p, and SKS660p. (a) deconvolved L component (SRFL). (b) deconvolved Q component (SRFQ).

The synthetic tests for the 1-D velocity model indicate that the GC_SRF strategy can successfully recover the Sp converted phases (see Figure 7). Notably, the Q-component (SRFQ) plot in Figure 7c has been suggested to reflect information on the earthquake sources (Vinnik et al., 2004; Kawakatsu et al., 2009). It is also evident that the Smp seismic phase is highly consistent at 5 s for the three models, as they all possess the same crustal thickness. Other notable features are the significant time shifts in the SLp phases for the three models and the fit of the peaks of the SLp phases to the theoretical travel time (see Table 1) within a certain range of epicentral distances (60°–80°). Furthermore, the results demonstrate that many other Sp

272 phases, such as S410p, ScS410p, ScS660p, SKS410p, and SKS660p, can be rebuilt without
273 artifacts.

274

Model name	Epicentral distances (degree)	t_{Smp}-t_S (s)	t_{SLp}-t_S (s)
SM01 Moho 40km LAB 120km	60	-5.85	-17.04
	65	-5.74	-16.35
	70	-5.64	-15.82
	75	-5.55	-15.35
	80	-5.47	-14.96

275 **Table 1** The synthetic time residual of Smp to S and SLp to S. The waveforms with epicentral
276 distance of 75° are shown in Figures 6, S1 and S2.

277 3.2 Application to a two-dimensional (2-D) velocity model and post-stack migration

278 The robustness of the imaged discontinuities needs to be further demonstrated to ensure
279 that a reliable lithospheric thickness is obtained; we therefore perform a resolution test for the 2-

280   D case via forward modeling. We first construct a 2-D velocity model that is modified from

281   IASP91 (Figure 8a) and calculate the full wavefield seismograms for a pseudo profile using 10

282   stations. The GC_SRF strategy is then used to calculate SRFs. A wave equation-based post-stack

283   migration method (Chen et al., 2005a; b) is employed for this resolution test. The moveout-

284   corrected SRFs are first processed using time-domain common conversion-point (CCP) stacking,

285   and the stacked SRFs are subsequently processed using frequency-domain backward wavefield

286   extrapolation to obtain the migrated images (Chen, 2009; Chen et al., 2009). We use rectangular

287   stacking bins when performing CCP stacking. The bin width, which is perpendicular to the

288   profile, is set to 200 km, whereas the bin length, which parallels the profile, varies with depth

289   and data coverage. The modeling results (Figure 8b) show that the interface morphology in the

290   theoretical velocity model can be recovered by migrating the SRF obtained by the GC_SRF

291   strategy. The resolution test also indicates that the GC_SRF strategy is capable of obtaining

292   reliable SRFs without artificial interference.
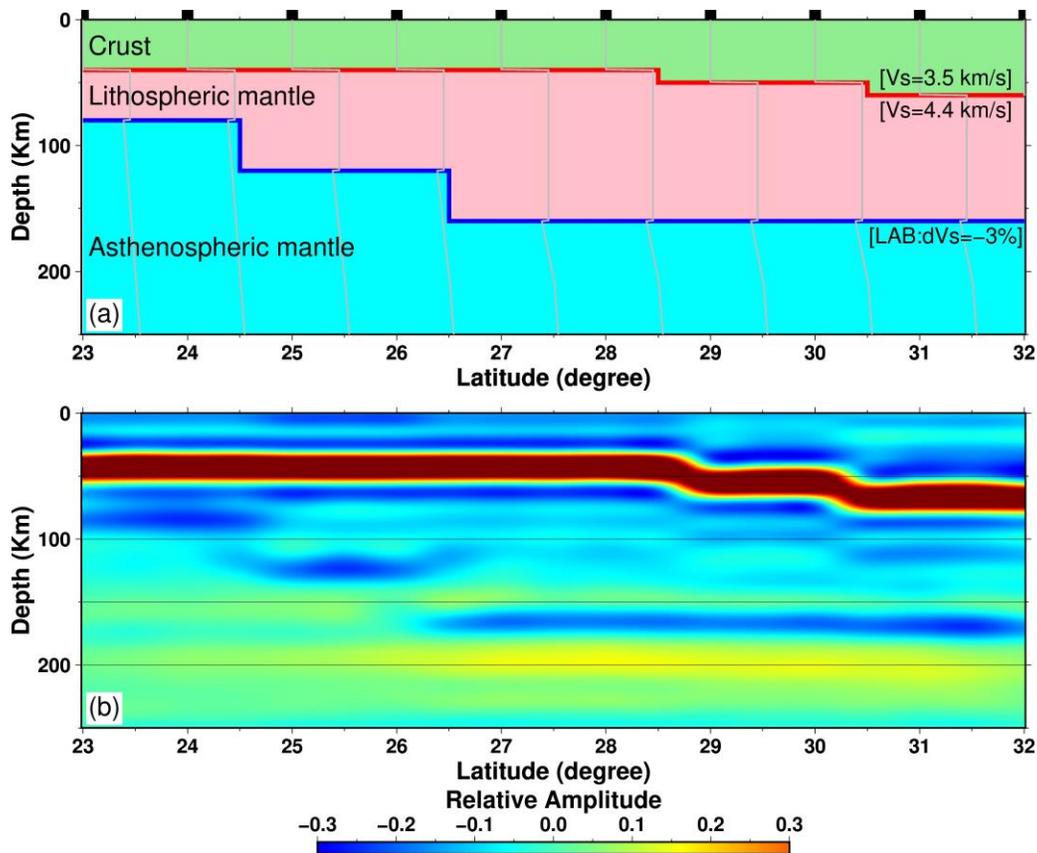

293

294   **Figure 8:** Synthetic test for 2-D velocity model. (a) Synthetic velocity model modified from

295   IASP91. The black boxes on the frame show the pseudo stations where the 1-D velocity curves

296   are plotted in gray. The red line indicates the Moho discontinuity, and the blue line represents the

297   LAB discontinuity. Velocity changes at discontinuities are labeled. (b) Post-stack migrated

298   image of the GC_SRF results. The cutoff frequency limit is set to be 0.05-0.25Hz.

**4 Application to stations in southeastern Tibet**

300   It is necessary to test this strategy in a given region to validate its applicability and

301   feasibility in LAB detection. Here we apply the GC_SRF strategy to seismic stations in

302   southeastern Tibet, a collision area between the Eurasian and Indian plates. This area is adjacent

303   to the Sichuan Basin in the east, and spans the Tengchong Volcano region and Permian

304   Emeishan Large Igneous Province. Furthermore, this area is widely believed to possess channels

305   that promote the eastward escape of materials from the Qinghai-Tibet Plateau (Molnar &

306   Tapponnier, 1975; Tapponnier et al., 1982). Several large-scale geophysical investigations have

307   previously been conducted across this region, including surface-wave tomography (e.g., Yao et

308   al., 2008; Huang et al., 2013; Yao, 2020), body-wave tomography (e.g., Lei et al., 2014; Lei &

309   Zhao, 2016), and PRF imaging (e.g., Xu et al., 2013; Ye et al., 2017).

310   Recent Rayleigh-wave tomographic results have shown that a high-velocity pattern is

311   present at the LAB depth under the Chuandian region (Fu et al., 2017), whereas a body-wave

312   tomographic study (Huang et al., 2019) has revealed a low-velocity pattern at the same depth

313   range. Deng et al. (2021) obtained an independent constraint on the architecture via body-wave

314   attenuation tomography, which suggested that the Sichuan Basin and Chuandian region possess

315   the same extremely low attenuation structure. The Sichuan Basin belongs to an ancient craton

316   and should have a relatively thick lithosphere, whereas Tengchong Volcano should have a

317   relatively thin lithospheric thickness due to the underlying hot mantle (Sun et al., 2013; Deng &

318   Tesauro, 2016). It is generally believed that a low velocity (Lei et al., 2009), high attenuation

319   (Byrnes et al., 2019), and low effective elastic thickness (Chen et al., 2013) correspond to a thin

320   lithosphere, whereas a high velocity, low attenuation, and high effective elastic thickness

321   correspond to a thick lithosphere. However, the lithospheric thickness in this region remains

322   unresolved. Although a few traditional receiver function methods have been used to determine

323   the LAB depth distribution (Zhang et al., 2010; Hu et al., 2011; Zhang et al., 2018) in this region,

324   the results are hard to reproduce because they have quite different values, which may be due to

325   artificial interference, even though they follow a similar pattern. Therefore, a robust and

326 quantitative analysis of the lithospheric thickness in this region is of great significance for
327 understanding its tectonic evolution.

328   4.1 GC_SRF-based data processing approach

329   The analyzed teleseismic S waveform data were collected from 60 permanent stations
330 between 86°–111°E and 22°–96°N (Figure 9) during the January 2010–December 2015 period
331 (Zheng et al., 2010). We selected teleseismic S waveforms from Ms ≥ 5.5 earthquakes that
332 occurred at epicentral distances of 50°–90° and possessed SNR_H greater than 5 for the GC_SRF
333 approach. We obtained 18239 SRFs with clear Sp phases from 879 seismic events after the
334 preprocessing steps (see Methods section) and deconvolution.

335
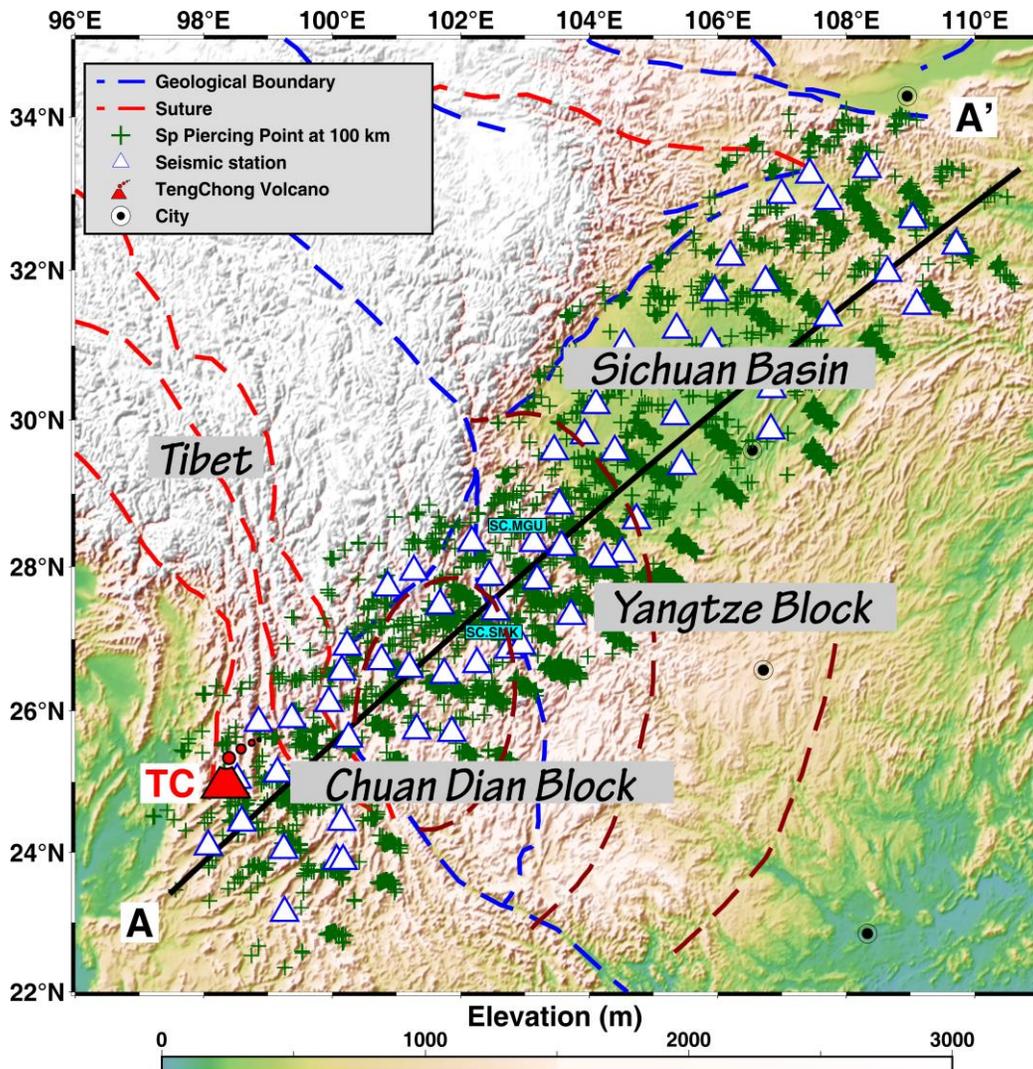

Figure 9: Topography of southeastern Tibet and adjacent regions. White triangles with blue lines represent the 59 stations used in this study. The black solid line represents the location of the migration profile A-A'. Dark-green crosses mark the piercing points of the corresponding SRFs at 100 km. Blue dashed lines mark geological boundaries. Red dashed lines represent suture belts. Dark red circular lines outline the inner, middle, and outer zones of the Permian Emeishan Large Igneous Province. Abbreviations: TC, Tengchong Volcano.

We then reversed the time axis and performed RMSE reordering, followed by CCP stacking and migration. Different RMSE percentages (5%–100%) were tested in our estimations, with an example from station SC.MGU shown in Figure 10. Figure 10a and 10b show the SRFs before and after RMSE reordering, respectively, Figure 10c shows the change in RMSE with index number, and Figure 10d and 10e show the stacked waveforms for different RMSE percentages. These two latter figures show that the RMSE percentage directly affects the amplitudes of both the Smp and SLp phases. Previous studies (Farra & Vinnik, 2000; Hansen et al., 2009; Abt et al., 2010) have indicated that a consistent and robust Smp phase can be considered the premise for discussing the SLp phase. After comparing other percentages, the selection of 30% ensures that the SLp seismic phase can be significantly distinguished under the condition that the Smp phase is as clear as possible. We finally chose the SRF dataset with a 30% RMSE percentage for the CCP stacking and migration steps to ensure the reliability of the stacked waveform.
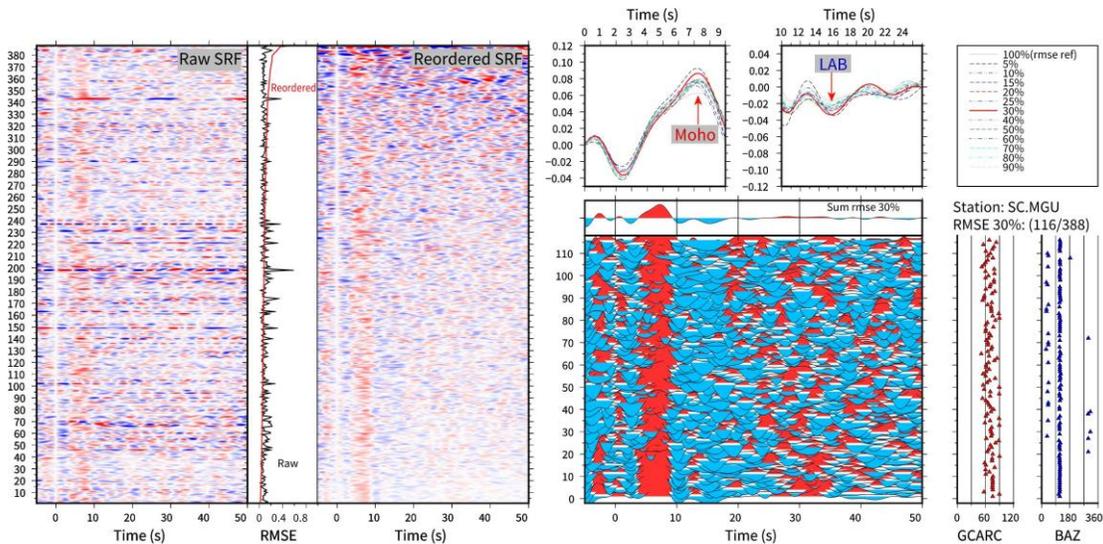

356   **Figure 10:** The reordered SRFs based on RMSE at station SC.MGU. (a) Raw SRFs after

357   deconvolution. (b) the RMSE values corresponding to each SRF. The black line shows the

358   RMSE of the raw sequence, while the red for reordered ones. (c) reordered SRFs based on

359   RMSE. (d) and (e) present the Smp phase and SLp phase corresponding to different RMSE

360   percentages. (f) SRFs of 30% RMSE percentage, and the top waveform indicates with the

361   summation of these waveforms. The epicentral distance (GCARC) and back-azimuth (BAZ) for

362   each event as well as the total number of SRFs are listed in (g) and (h).

363   4.2 Post-stack migration results in southeastern Tibet

364   Post-stack migration is performed in the same way as that in the 2-D synthetic test. A

365 modified 1-D IASP91 velocity model that is based on the adjacent crustal structure (Yao, 2020)

366 was used to calculate the delay times and piercing points and perform the frequency-domain

367 wavefield extrapolation. We separately selected 0.03 Hz and 0.05 Hz as the lower cutoff

368 frequency limits (Zhang et al., 2018; Zhang et al., 2019) and 0.2 Hz and 0.25 Hz as the upper

369 cutoff frequency limits to reduce the noise and illuminate the LAB depths.

370   The most prominent features in the CCP cross-section are the positive Moho phases (red-

371 filled seismic waveforms in Figure 11a) at approximately 5–8 s, which can be continuously

372 traced along the section. There are discontinuous negative phases (cyan-filled waveforms in

373 Figure 11a) between approximately 10 and 25 s under the shallow positive Moho phase

374 conversions. The post-stack migration results for different frequency contents, 0.03–0.2 Hz

375 (Figure 11b), 0.03–0.25 Hz (Figure 11c), and 0.05–0.25 Hz (Figure 11d), possess discontinuity

376 patterns that are similar to those in the CCP image (Figure 11a). The discontinuous negative

377 (blue) layer exhibits larger variations at depth than the overlying continuous positive (red) layer.

378
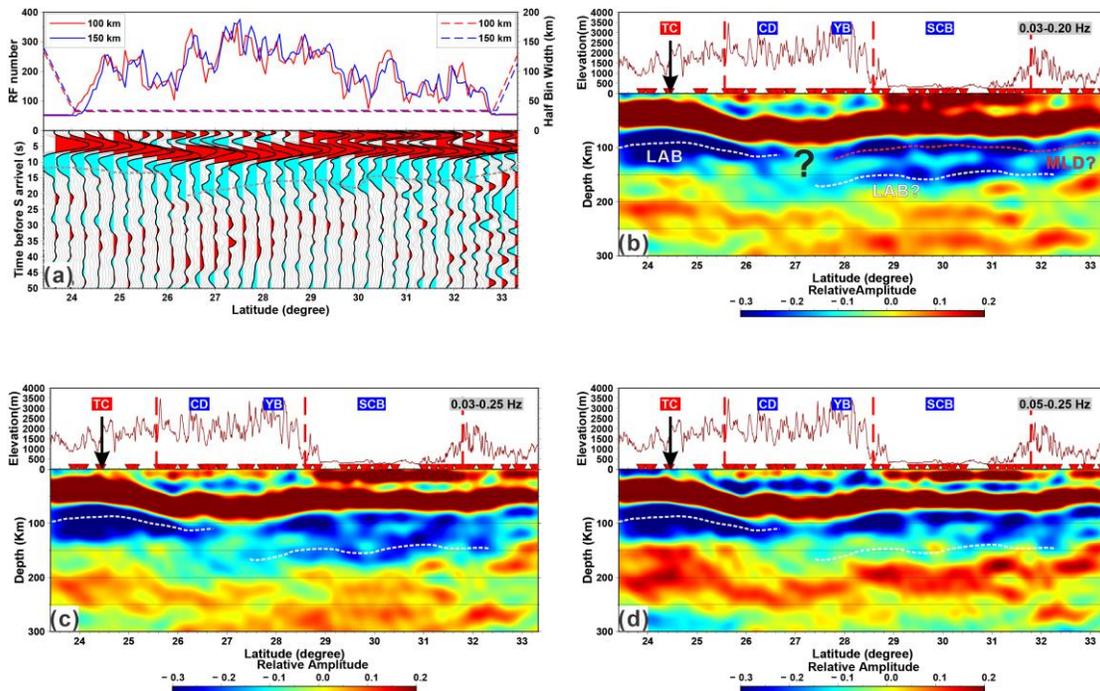

Figure 11: Common conversion point (CCP) stacking profile and post-stack migration image profile along A-A' shown in Figure 7. (a) Stacked sections of S (0.03–0.5 Hz) receiver functions after moveout corrected to epicentral distance of 0. The coherent negative SLp phase is traced by gray dashed lines. The Top panel presents the RF number and half width for each bin. (b-d) post-stack migration SRF images. Different frequency contributions of the data were considered in imaging: (b)0.03-0.2Hz; (c) 0.03-0.25Hz; (d) 0.05-0.25Hz. On each top panel, the red solid lines show the topography, and the red dashed lines represent geological boundaries. The white dashed lines on the bottom panel of (b-d) indicate LAB while the red dashed line in (b) presents the possible mid-lithospheric discontinuities (MLDs).

4.3 Geodynamic implications of the lithospheric structure

It is known that the SLp phase is usually submerged in the Smp sidelobe, as discussed in previous studies (Li et al., 2007; Kumar et al., 2012; Shen et al., 2019; Kind et al., 2020). We evaluated the robustness of the Moho and LAB depths using the criteria proposed by Zhang et al. (2018); we only discuss the primary characteristics in this section. We carefully determined the negative phase that is adjacent to the Moho as the LAB signal, which is traced by the dashed gray line in Figure 11a. However, whether the negative phase between Moho and LAB can be interpreted as a mid-lithospheric discontinuity (MLD), such as the MLD observation beneath the

396 North China Craton (Chen et al., 2014; Sun & Kennett, 2017), is a key issue that we plan to
397 address in future research. We prefer to interpret the shallow visible strong negative phase below
398 Moho under the Sichuan Basin as an MLD based on previous and recent lithospheric thickness
399 results at Tengchong Volcano (Huang et al., 2002; Lei et al., 2009; Zhang et al., 2015) and the
400 Sichuan Basin (Zhang et al., 2010; Chen et al., 2013; Huang et al., 2014).

401 The mid-crustal positive velocity gradient (PVG) is widely interpreted to be the result of
402 thick sediment cover, as observed in other basins (Li et al., 2007; Chen et al., 2009; Mohsen et
403 al., 2011; Tao et al., 2014). Recent research has suggested that the sediment cover across the
404 Sichuan Basin ranges from 6 to 13 km in thickness (Xia et al., 2021). Our results indicate a
405 discontinuous distribution pattern of the PVG that is concentrated mainly in the Sichuan Basin
406 area. It is interesting that the spatial distribution range of the PVG is consistent with the range of
407 low elevations within the basin area; we therefore interpret the PVG to represent the basement of
408 the Sichuan Basin sediments.

409 A thick crust lies beneath the Sichuan Basin (~50 km), whereas a thin crust lies beneath
410 Tengchong Volcano (~40 km), with the thickest crust observed in the Chuandian region (~60
411 km; Figure 11b). This pattern is consistent with comprehensive geophysical investigations that
412 revealed magmatic underplating beneath the Chuandian region (Xu et al., 2014; Chen et al.,
413 2015; Deng et al., 2016), even though the SRF uncertainties are larger than the uncertainties
414 associated with the PRF and active seismic results. Furthermore, our study highlights a
415 lithospheric thickness of ~160 km beneath the Sichuan Basin, with a thickness of ~90 km
416 beneath Tengchong Volcano. The discontinuity patterns of the crust and lithosphere are
417 consistent with previous SRF studies (Hu et al., 2011; Peng et al., 2021) in the same region;
418 however, our results are obtained without any artificial interference. Previous studies have
419 employed receiver function, ambient noise tomography, and body-wave and surface-wave
420 tomography methods to clarify both the Moho discontinuities and LAB near our study region
421 (Zhou et al., 2012; Wang et al., 2021; Wei et al., 2022), with each of these studies suggesting a
422 thin crust and thin lithosphere beneath Tengchong Volcano. A thick (150–180 km) lithosphere
423 that underlies a crustal lid (35–50 km) that has also been observed beneath the Sichuan Basin
424 (Zhang et al., 2010; Wang et al., 2018; Zhang et al., 2018), with the thick lithosphere beneath the
425 basin being a typical characteristic of this ancient craton (Li et al., 2021; Xu et al., 2021).

426   However, the LAB beneath the Chuandian region is not clear compared with that of
427   Sichuan basin and Tengchong Volcano. Permian Emeishan flood basalts have been emplaced
428   beneath the Chuandian region, with the lack of a detectable LAB aligning directly beneath the
429   inner zones of the Permian Emeishan Large Igneous Province. The mantle plume model is a
430   popular approach for explaining the geophysical and geochemical observations (Xu et al., 2007;
431   Chen et al., 2015; Deng et al., 2016; Li et al., 2021) in large igneous provinces. The plume head
432   could undergo strong changes and erode the overlying lithosphere owing to high temperatures
433   and push it upward, with this being a common type of lithospheric thinning caused by a rising
434   plume (Burov et al., 2007; Hawkesworth et al., 2017); this phenomenon is known as plume-
435   induced lithospheric destruction. However, the lithosphere could undergo downgrowth through
436   cooling, as demonstrated in North America (Yuan & Romanowicz, 2010; Hawkesworth et al.,
437   2017). A recent study has also shown that the plume could also recratonize the lithosphere,
438   mainly through compositional changes, as demonstrated in Arctic Canada (Liu et al., 2021). This
439   newly generated LAB possesses a smaller velocity jump than the old LAB, such that its
440   amplitude is smaller than that beneath the Sichuan Basin. We therefore suggest that the unclear
441   LAB beneath the Chuandian region indicates regrowth of the modified lithosphere owing to
442   mantle plume processes, which in turn produced the unique seismic velocity pattern, low
443   attenuation, and high resistivity in this region (Li et al., 2020; Deng et al., 2021).

444   **5. Conclusion**

445   We proposed a new strategy, the GC_SRF strategy, to obtain the lithospheric thickness
446   without artificial interference. We precisely determined the parameters in obtaining SRFs and
447   avoided possible artifacts by employing grid search and correlation analysis. The 30% RMSE is
448   employed to do the quality control. The synthetic tests indicate that this GC_SRF strategy can
449   obtain reliable SRFs from full wavefield seismograms. Our application of the GC_SRF strategy
450   in southeastern Tibet demonstrates this strategy yields excellent statistical consistency in single-
451   station analysis. The migrated image shows that the Chuandian region possesses the thickest
452   crust in the study area, followed by the Sichuan Basin, with the thinnest crust located beneath
453   Tengchong Volcano. Furthermore, a thick lithosphere beneath the Sichuan Basin (~160 km) and
454   a thin lithosphere beneath Tengchong Volcano (~90 km) have been clearly imaged. Another
455   notable finding is that the LAB signal is unclear beneath the Chuandian region, which is

456 interpreted to indicate lithospheric regrowth after modification of the Emeishan mantle plume.

457 These combined results suggest that this new strategy is suitable for obtaining SRFs and

458 constraining the lithospheric thickness without artificial interference. This strategy can be widely

459 applied to other regions for obtaining the lithospheric thickness and advancing our understanding

460 of lithospheric evolution. The influences of different velocity jumps on the SRF amplitude

461 warrant future research.
