Key Points:

- Highly elevated CH_4 (up to 250 ppm) and CO_2 (up to 640 ppm) in subglacial air indicate high emissions of both gases from below the ice sheet

- Gaseous CH_4 and CO_2 originate from gases dissolved in the meltwater.

- The isotopic signature and composition of subglacial CH_4 in gas and meltwater show that it originates from microbial acetate fermentation

- Isotopic signatures of subglacial gCO_2 indicate that both methane oxidation and remineralisation are likely subglacial sources of CO_2

20 **Abstract**

21 Emission of methane (CH_4) and carbon dioxide (CO_2) from the subglacial environment under

22 Greenland Ice Sheet (GrIS) was only recently discovered. The understanding of mechanisms and

23 magnitudes of emissions, and the origin of the gases, is extremely sparse. This study reports the

24 magnitude and temporal variations in net emissions at the onset, near maximum and at the end of

25 the melt season in 2018 and 2019 and investigates the possible origin of the subglacial CH_4 and

26 CO_2. *In situ* mole fractions of CH_4 and CO_2 were measured in the subglacial air at a subglacial

27 river outlet where emissions of CH_4 and CO_2 had been identified. Water samples were analysed

28 for dissolved CH_4 and CO_2 concentrations. CH_4 and CO_2 in gas and water samples were

29 analyzed for their isotopic composition of ^{13}C and ^2H. Close correlation between gaseous and

30 dissolved CH_4 and CO_2, respectively, show degassing of CH_4 and CO_2 from the subglacial

31 meltwater. The diurnal variability of *in situ* mole fractions of CH_4 and CO_2 in subglacial air was

32 related to meltwater runoff. Maximum *in situ* mole fractions decreased after the peak of the melt

33 season, but estimated net emissions increased because the size of the subglacial river outlet

34 increased. The isotopic signature of CH_4 in the subglacial air, estimated with a Keeling plot,

35 indicated that subglacial CH_4 likely originated from acetoclastic methanogenesis. Isotopic

36 signatures of gaseous CO_2 indicate that both microbial oxidation of CH_4 in the subglacial system

37 and remineralization of carbon in subglacial sediments contribute to subglacial CO_2.

38 **Plain Language Summary**

39 Wetlands and thawing permafrost are considered to be the primary sources of natural

40 methane and carbon dioxide emissions in the Arctic. However, new discoveries show that these

41 gases are also emitted in large quantities from the meltwater coming from under the Greenland

42 Ice sheet. So far, subglacial gas emissions have only been investigated at two sites in Greenland

43 and it is not known how much gas is released, where it comes from and how sensitive the

44 emissions are to future climate change. The aim of our research is to investigate how much is

45 emitted to the atmosphere and what the likely origin of these gases are. Our field measurements

46 show that the levels of methane and carbon dioxide in the glacial outlet cavity are up 100 times

47 higher than the background levels of methane in the atmosphere. Our results show that these

48 gases originate from biological processes under the ice, and that the release rate is controlled by

49 the melting of the glacier. Our study reveals new insight in to this unknown Arctic source of

50 greenhouse gases which will help us to understand its broader relevance for the atmospheric

51 composition and its feedback to climate change.

1 Introduction

53   Ice sheets and glaciers separate large parts of the earth's rocky surface and sediment

54 deposits from the atmosphere. Until recently it was perceived that glaciated areas had no

55 significant impact on the glocal carbon cycle and that only little carbon was exchanged across

56 this separating layer. Recent research results have challenged this view by showing that large

57 exports of both methane (CH_4) and carbon dioxide (CO_2) can occur from subglacial

58 environments (Burns et al., 2018; Christiansen & Jørgensen, 2018; Lamarche-Gagnon et al.,

59 2019; Pain et al., 2020). Estimates show that the subglacial CH_4 export in melt water from the

60 Leverett glacier draining the Greenland Ice sheet (GrIS) can rival those of major world rivers

61 (Lamarche-Gagnon et al., 2019). This points to an overlooked, and likely significant, source of

62 CH_4 and CO_2 emissions to the atmosphere, which is a natural constituent of the global carbon

63 cycle that may be affected by global climate change.

64   Elevated concentrations and biological production of CH_4 in subglacial waters and

65 sediments have been found under glaciers and ice sheets across Canada (Hamilton et al., 2013),

66 Antarctica (Michaud et al., 2017; Stibal et al., 2012), West Greenland (Dieser et al., 2014),

67 Iceland (Burns et al., 2018) and at the center of the GrIS (Christner et al., 2012; Souchez et al.,

68 1995). Once formed under the ice, the CH_4 may either be stored as dissolved gas in the basal

69 meltwater or accumulate as hydrates under high pressure (i.e. solid CH_4 bound in a crystal

70 structure with water molecules) (Wadham et al., 2012) both of which eventually will be exported

71 to the proglacial zone via meltwater rivers and emitted to the atmosphere. Microbial potential to

72 oxidize subglacial biological CH_4 to CO_2 has also been documented in sediment and water

73 samples from below the GrIS and Antarctica (Dieser et al., 2014; Michaud et al., 2017).

74 These findings point to the potential occurrence of widespread subglacial biological processes

75 responsible for production of CH_4 and CO_2 that can be emitted to the atmosphere. Organic

76 carbon reserves in overridden paleosoils (Kohler et al., 2017) or marine sediments (Wadham et

77 al., 2012) below ice sheets worldwide could surpass the amount stored in non-glaciated

78 permafrost areas (Wadham et al., 2019). If this carbon is or becomes available to microbial

79 degradation into CH_4 and CO_2 in the subglacial environment it potentially represents a large, but

80 little known emission magnitude of these gases to the atmosphere.

81   The very limited empirical evidence from field studies on subglacial CH_4 and CO_2

82   turnover processes and emissions (Burns et al., 2018; Christiansen & Jørgensen, 2018;

83   Lamarche-Gagnon et al., 2019) is insufficient for understanding of the importance of subglacial

84   carbon conversion for the atmospheric CO_2 and CH_4 composition and whether it can be regarded

85   as potential climate amplifier (Wadham et al., 2008, 2019). In this paper we present new findings

86   from field work carried out in the summers of 2018 and 2019 adding to fill our knowledge gap

87   on subglacial carbon emission rates and turnover processes. We performed *in situ* high frequency

88   measurements of the mole fractions of CH_4 and CO_2 in the subglacial air inside the air-filled ice

89   cavities found at the ice edge, and collected discrete gas and water samples for analyses of the

90   isotopic composition of CH_4 and $CO_2.$ The aims were to 1) measure the magnitude of subglacial

91   carbon fluxes to the atmosphere at the onset, near maximum and late stages of the melt season,

92   2) to study the diurnal and seasonal temporal dynamics of subglacial CO_2 and CH_4 emissions and

93   their relation with glacial hydrology, and 3) to investigate the potential sources of subglacial CH_4

94   and CO_2.

95   **2 Materials and Methods**

96   2.1 Site description

97   The study site is located at an elevation of 450 m above sea level at a lateral subglacial

98   meltwater outlet on the southern flank at the terminus of the Isunnguata Sermia Glacier at the

99   western margin of the GrIS (67°09'16.40''N 50°04'08.48''W).

100   The area in front of the meltwater outlet consists of abraded granodioritic gneiss bedrock

101   with large boulders and patches of gravel, sand and silt deposited by meltwater. The glacier front

102   contained highly irregular cracks and air-filled cavities, which changed over the season as the ice

103   melted and deformed (Figure 1).

104   The landscape in the Kangerlussuaq area is typical of west Greenland, where numerous,

105   narrow and up to 600 meter deep valleys are oriented in a East - West direction. These valleys

106   extend below the ice sheet, and subglacial valleys can in places reach depths of hundreds of

107   meters below sea level. Deglaciation and re-advance of the GrIS in this region during the

108   Holocene has resulted in buried subglacial carbon rich sediments that were once exposed

109   (Kellerman et al., 2020; Kohler et al., 2017). In the proglacial zone of the study area continuous

110   permafrost extends at places up to 350 meters below the surface (Drake et al., 2017), but the

111   Isunnguata glacier and GrIS in this area is warm based with an annual ice flow of 150-200

112   meters and surface meltwater reaching the base of the glacier (Graly et al., 2014).

113   We sampled melt water and gas at a lateral subglacial outlet to the Isunnguata Sermia

114   glacier draining the GrIS in West Greenland (Figure 1 top panel). The sampling was done during

115   three campaigns covering the periods May 3rd to 6th 2019, June 18th to 28th and August 16th to

116   24th 2018, during which the cross sectional area of the subglacial outlet changed size and

117   position along the ice edge (Figure 1a-c). These periods are assumed to represent the early,

118   middle and late stages of a typical melt season.

119   2.2 Measurements of subglacial air velocity, temperature, humidity, atmospheric pressure and

120   water level

121   At the end of an aluminium pole that extended under the ice for retrievel of unmixed

122   subglacial air we attached instrumentation to measure subglacial air velocity (hot-wire

123   anemometer, model 313-T-DCI-F900-L-O, Onset Computer Cooperation, USA), temperature

124   and humidity (model 313-S-THB-M008, Onset Computer Cooperation, USA). The anemometer

125   was positioned so it measured the wind movement perpendicular to the cross section.

126   Atmospheric pressure was measured outside the cave (model 313-S-BPB-CM50, Onset

127   Computer Cooperation, USA). The data were recorded on a HOBO datalogger (model U30-

128   NRC-VIA-05-S100-000, Onset Computer Cooperation, USA) at 10 second intervals. These

129   measurements were conducted during the June and August campaigns only. We were only able

130   to measure the air velocity for a short period in June as the sensor was damaged by water spray

131   in the ice cave.

132   During the August 2018 campaign, we also installed an underwater pressure transducer

133   (Onset Computer Corporation, USA) in the outlet stream to estimate the temporal variability of

134   the water level. Air pressure from the meteorological station was used as the atmospheric

135   reference needed to calculate the water level above the pressure transducer. The water level was

136   assumed as a proxy for melt water runoff, but the discharge volume was not estimated.
Figure 1 Top panel: Map of West Greenland and Isunnguata glacier with study site indicated at red squares (top left inset) and an overview of the study site at the ice front in June 2018. Letters (a, b, c) indicate location of measurement of mole fractions of CH₄ and CO₂ in subglacial air and sampling of melt water at three different stages during the melt season. a) May 2019 represents the early stage meltwater discharge where the meltwater openings are small and mostly filled with water. b) June 2018 represents a progressive stage of opening where multiple cracks and caves are air filled after the meltwater has carved out channels in the ice. c) August 2018 represents the mature stage of evolution of the meltwater channel, where the volume of the outlet is at its maximum and most of it is air filled due to decreasing meltwater volumes.

146   2.3 Measurements of gaseous subglacial CH_4 and CO_2 mole fractions and flux calculation

147   Dry mole fractions of CH_4 and CO_2 in the subglacial air were measured with a portable

148    $CH_4/CO_2/H_2O$ analyzer (Ultraportable Greenhouse Gas Analyzer (UGGA), ABB Los Gatos

149   Research, USA) powered by a 12 V 100 Ah LiFePO4 battery. Due to shifting positions and

150   geometries of the subglacial cave, the gas sampling setup with the UGGA was not identical

151   during all campaigns, but generally followed the same procedure (Figure 1a-c). The cross

152   sectional areas of the outlet during the three campaigns were estimated based on field

153   observations of the dimensions (height and width) of the opening (Figure 1a-c). Gas

154   measurements were performed by attaching a tube to a 9 m aluminium pole and sampling the air

155   inside the subglacial cavities (Figure 1a-c). A water trap fixed to the end of the aluminium pole

156   ensured a liquid free air stream to the gas analyzer.

157   The net CH_4 and CO_2 emission (g CH_4 s^{-1} or g CO_2 s^{-1}) across the entire cross sectional

158   area from the subglacial cave to the atmosphere was calculated as a mass flow of air through the

159   estimated cross section area according to equation 1:

160    $$F_{CO_2/CH_4} = C * \bar{\upsilon} * A * \frac{273.15}{(M_v * T_a)} * M * 10^{-6} \qquad \text{(equation 1)}$$

161   Where C is the measured 0.1 Hz dry mole fraction (µmol mol^{-1}) of CO_2 or CH_4, $\bar{\upsilon}$ is the wind

162   speed (m s^{-1}) measured every 10 seconds perpendicular to the cross section, A is the cross

163   sectional area at the given measurement period (m^2), M_v is the molar volume (m^3 mol^{-1}), T_a is the

164   air temperature (°K) measured in the cavity, M is the molar mass of CO_2 or CH_4 (g mol^{-1}), the

165   constant 10^{-6} converts the flux from µg to g CO_2/CH_4. The cross sectional area was estimated

166   based on the width and height measured in the field (Figure 1a-c). To estimate and compare the

167   net CH_4 and CO_2 emission between campaigns we assumed that the average wind speed

168   (0.8 ± 0.28 m s^{-1}) measured in June 2018 and air temperature (0.2°C) in the cavity was similar

169   between and constant during the three measurement periods. The average hourly net emission for

170   each measurement period was then calculated as the sum of 0.1 Hz emissions over the

171   measurement period divided by length in hours of the measurement periods. This approach

172   provide at best a rough and uncertain estimate, referred to as "plausible range", and was

173   calculated as the emission for the minimum wind speed at the minimum cross section area and

174   maximum wind speed for the maximum cross section area. The impact of short term influx of

175   CH_4 and CO_2 from the atmosphere to the cave, due to turbulent mixing, was accounted for by

176   averaging the 0.1 Hz effluxes over the measurement period.

177   2.4 Collection of discrete water and gas samples

178   Water and gas samples were taken at three different locations after the subglacial water

179   and air had mixed to different degrees with the ambient environment. For the air samples, the

180   simultaneous variations in mole fraction and isotopic composition were used to determine the

181   isotopic composition of the source ($\delta^{13}C$-CH_4, δ^2H-CH_4 and $\delta^{13}C$-CO_2) of the subglacial CH_4 and

182   CO_2 using the Keeling plot approach. This is a widely used method to determine the isotope

183   composition of unknown sources of CO_2 or CH_4 in situations where CH_4 or CO_2 from a source

184   (in our case the subglacial environment) is added to a constant background (atmosphere) (Pataki

185   et al., 2003).

186   Water and gas were sampled twice per day, in the morning and evening, assumed to

187   represent low and high water flow derived from the water level measurements. In 2018, samples

188   were gathered during the periods 22nd – 26th June and 19th – 22nd August.

189   Air samples were collected in 2L gas tight aluminium foil bags (Supel™-Inert Multi-

190   Layer Foil, Sigma-Aldrich, USA) which were filled by a small diaphragm pump. We sampled

191   gas from three locations (Figure 1a-c); inside the ice cave, representing the least mixed

192   subglacial air we could possibly sample (minimal mixing with atmosphere), right outside the ice

193   cave (subglacial air mixed with atmospheric air) and 2 km from the ice edge (background

194   atmosphere, no subglacial air signal).

195   For practical reasons the water was sampled at slightly different positions than the gas.

196   Thus, the first water sample representing the subglacial water was sampled right where the

197   meltwater exists the ice (PW1), the second sample (PW2) 200 meter downstream and the third

198   sample was taken at the same position as the third gas sample, 2 km away from the ice edge

199   (PW3). Unfiltered water was sampled in 120 mL glass bottles with butyl rubber septa and

200   tightened with aluminium screw caps. The bottles were rinsed three times with melt water and

201   filled under water ensuring that no bubbles were included. Immediately after sampling, 12 μL

202   saturated $HgCl_2$ solution was added to the bottles to exclude further biological activity (Magen et

203   al., 2014). Water was sampled in duplicates, one sample for measurement of dissolved CH_4 and

204   another for measurement of CH_4 isotopic composition.

205   Gas and water samples were stored cold and dark until analysis, except during transport

206   from Greenland to Denmark where samples were transported in the cargo hold of the airplane.

207   Transport resulted in loss of three gas samples, but water samples remained intact. Upon arrival

208   in Denmark the gas bags were immediately sent to Utrecht over land and transferred to glass

209   bottles for longer term storage until isotopic analyses were possible. The total time from

210   sampling to extraction was up to 14 days.

211   2.5 Dissolved CH_4 concentrations

212   The dissolved CH_4 was extracted using headspace mixing and the concentration was

213   calculated according to the method outlined in Magen et al. (2014). Shortly, 10 mL of water

214   (V_{HS}) was replaced with CH_4 free N_2 gas and the headspace was afterwards pressurized to 2

215   atmosphere (P_{HS}), by adding another 10 mL N_2 amounting to 20 mL of gas in the headspace

216   (V_{gas}). The sample was then thoroughly stirred on a shaking table with 150 RPM for three

217   minutes. A 5 mL gas sample was retrieved by syringe from the headspace and transferred to an

218   evacuated 3 mL exetainer with a butyl rubber screw cap (Labco, UK). The pressurization of the

219   exetainer was done to facilitate subsequent gas chromatography analysis. The CH_4 mole fraction

220   in the headspace (CH_4,mf) of extracted gas samples was determined on a gas chromatograph

221   equipped with an FID detector. CH_4 was separated on a HayeSep Q column heated to 60°C, with

222   pure N_2 5.0 as carrier gas. Using a five-point calibration curve the headspace CH_4 mole fraction

223   in ppm was determined. The total dissolved CH_4 was calculated as the sum of the headspace CH_4

224   and CH_4 still dissolved in the water after shaking (Magen et al. 2014). The ideal gas law was

225   used (laboratory temperature at extraction was 23°C) to convert the headspace concentration to

226   gas amount (mole) (equation 2). The dissolved CH_4 in the remaining 110 mL water was

227   calculated by multiplying the Bunsen coefficient for 0°C (water temperature at sampling) at zero

228   salinity (assumed as we have no data) with the amount of headspace CH_4 to calculate the

229   remaining dissolved CH_4 in water (Yamamoto et al., 1976), accounting for the ratio of water and

230   gas volume (Magen et al., 2014) (equation 3).

231    $$CH_{4,HS} = CH_{4,mf} * V_{HS} * \frac{P_{HS}}{R*T_{HS}} \ [\mu mol \ L^{-1}] \hspace{3cm} \text{(equation 2)}$$

232    $$CH_{4,water} = \beta * \frac{CH_{4,conc} * V_{gas} * \frac{V_{water}}{V_{HS}}}{R*T_{water}} \ [\mu mol \ L^{-1}] \hspace{2cm} \text{(equation 3)}$$

233 Where $CH_{4,conc}$ is the headspace CH_4 mole fraction in ppm, V_{HS} is the headspace volume in L,

234 P_{HS} is the headspace pressure in atm, R is the gas constant (atm L K^{-1} mol^{-1}), T_{HS} is the

235 headspace temperature in °K, β is the Bunsen coefficient, V_{gas} is the total volume of gas in

236 headspace in L, V_{water} is the water volume after replacement in L, T_{water} is the water temperature

237 (similar to T_{HS}).

238 2.6 Dissolved CO_2 concentrations

239   Dissolved CO_2 in meltwater was measured *in situ* using an eosGP2 probe (Eosense Inc.,

240 Canada) connected to a Campbell CR1000 datalogger (Campbell Scientific Inc., USA) during

241 the June 2018 campaign. The sampling interval was 10 seconds and dissolved CO_2

242 concentrations given in ppm. A custom calibration for measurements at CO_2 concentrations close

243 to the atmospheric equilibrium had been done prior to the field work by Eosense. Before each

244 deployment, we let the eosGP2 probe equilibrate with the atmospheric background CO_2

245 concentration for approximately one hour to monitor possible drift and/or sensitivity of the

246 response of the CO_2 signal when switching the probe between the aqueous and gaseous phases.

247 At deployment the eosGP2 probes were fixed in place and the diffusion membrane initially

248 placed 15 cm below the surface of the meltwater at low flow conditions.

249 2.7 Isotopic analyses of gas and water samples

250   The isotopic composition of CH_4 ($\delta^{13}C$-CH_4, δ^2H-CH_4) was measured using continuous-

251 flow isotope ratio mass spectrometry (CF-IRMS) on a ThermoFinnigan Delta^{plus} XL isotope ratio

252 mass spectrometer. The air samples were injected via a mass flow controller into the sample loop

253 of the extraction system and further processed and analyzed as described in Röckmann et al.

254 (2016). The CH_4 in the water samples was extracted with a headspace mixing method and further

255 analyzed on the same analytical system, as described in Jacques et al. (2020). Further

256 information on the data processing is available in Brass and Röckmann (2010) and Sapart et al.

257 (2011). Specifically, the CH_4 isotopic data were corrected to account for system variability and

258 non-linearity effects and reported in ‰ vs VPDB for $\delta^{13}C$ values and ‰ vs VSMOW for δ^2H

259 values. The measurement reproducibility was calculated from the standard deviation of reference

260 air injections.

261   The isotopic composition of CO_2 ($\delta^{13}C$ and $\delta^{18}O$) was analyzed with the CF-IRMS

262   system described in Naus et al. (2018) and Pathirana et al. (2015). This system is primarily

263   meant for CO isotopes, but can also analyze CO_2 isotopes is small samples (~ 2 ml air at normal

264   atmospheric mole fractions). In short, the CO_2 is cryogenically separated from the air, further

265   purified chromatographically, and then injected into the IRMS via an open split inlet. The results

266   are related to the VPDB and VSMOW scales via a reference air cylinder with known isotopic

267   composition. The typical precision, estimated as repeatability of multiple measurements of a

268   constant gas (Target cylinder), is about 3 ppm for the CO_2 mole fractions, and 0.05 ‰ and 0.14

269   ‰ for $\delta^{13}C$ and $\delta^{18}O$ respectively.

3. Results and discussion

270

271   3.1 Subglacial CH_4 and CO_2 mole fractions and concentrations in air and meltwater

272   Figure 2 shows measured mole fractions of gaseous CH_4 (gCH_4) and CO_2 (gCO_2) (Figure

273   2a-c) and concentrations of dissolved CH_4 (dCH_4) (Figure 2d-f) for the three campaigns. During

274   all campaigns the gCH_4 and gCO_2 mole fractions measured at the outlet were continuously and

275   significantly elevated compared to the ambient mole fractions of these gases (Figure 2a-c). Also

276   in the water, dCH_4 concentrations are strongly elevated compared to the saturation concentration

277   of CH_4 (0.02 $\mu mol\ L^{-1}$) in contact with ambient air (Figure 2d-f). Collectively, this clearly

278   demonstrates that a source for these gases exists below the ice sheet.

279   Concentrations of dCH_4 were highest close to the outlet and decreased strongly with

280   distance from the outlet. Degassing is assumed to be the main loss process for dCH_4 from the

281   meltwater between the sampling points PW1 and PW3 (Christiansen & Jørgensen, 2018).

282   Oxidation of dCH_4 to CO_2 can contribute as well, but oxidation rates measured previously are

283   low (Dieser et al., 2014), indicating that it cannot be the main cause for the observed decrease

284   here. The dCH_4 at PW3 occasionally is lower than the atmospheric equilibrium during the June

285   and August 2018 campaigns, but it is not possible to determine if it is attributed to the inherent

286   uncertainty of dCH_4 determination or in-stream oxidation of CH_4 (Figure 2D-E).

287   In the June and August campaigns both CH_4 and CO_2 showed diurnal variability with

288   some inconsistency between the gases, which indicate that several factors contribute to this

289   observed variability (Figure 2A-C).

290   In June 2018, the temporal behavior of gCH_4 and gCO_2 were related to variations in melt

291 water and maximum mole fractions of both gases generally occurred at low flow conditions. A

292 possible explanation is that during the period of low water flow less surface water purges the

293 subglacial environment, and the dCH_4 and dCO_2, which presumably, are released at a constant

294 rate from the source under the ice, accumulates in this smaller volume of water, increasing the

295 concentrations. Degassing subsequently enriches the subglacial air with CH_4 and CO_2.

296 Additionally, the increase of melting during the day will dilute the CH_4 and CO_2 bearing

297 subglacial meltwater resulting in lower degassing and hence lower mole fractions in the

298 subglacial air at high water flow. The control of degassing on gCH_4 and gCO_2 mole fractions is

299 supported by simultaneous measurements of gCO_2 and dCO_2 in the June campaign (Figure S2A)

300 and water level for a single diurnal cycle. These measurements showed identical temporal

301 variability of dCO_2 and gCO_2, with maximum dCO_2 and gCO_2 occuring at low flow and higher

302 dCO_2 concentrations relative to gCO_2 (Figure S2) strongly suggesting that the meltwater is the

303 source of gCO_2.

304   In the August 2018 campaign the diurnal pattern of gCH_4 and partly that of gCO_2 were

305 slightly different than observed in June 2018 and anti-correlated to the flow variations observed

306 in the melt water river in August (Figure S1), with maximum gCH_4 and gCO_2 arriving at the

307 outlet on average 6 hours after minimum flow (Figure S1). At this waning stage of the melt

308 season the internal drainage system has reached its maximum volume, which may not be entirely

309 water filled because of lower melt rates. This could potentially leave air filled subglacial caves

310 where CH_4 and CO_2 can accumulate during low flux and the release to the atmosphere occurs

311 more slowly due to slower transport of the subglacial air compared to the melt water. In the early

312 stage of the melt season, where the drainage system volume is smaller and mostly filled with

313 water, most degassing more likely occurs closer to the outlet. In the May 2019 campaign, where

314 no visible caves had developed at the edge (representing the early melt season) diurnal variability

315 was difficult to discern.

316

330   Both the level and the temporal variability of gCH₄ mole fractions were different between

331   the seasons, with the highest average and maximum measured in May 2019, followed by June

332   2018 and the lowest average mole fractions in August 2018 (Table 1, Figure 2a-c). The average

333   enrichment factor (gCH₄/atmospheric CH₄) decreased from May to August from 35 to 9 (Table

334   1). For gCO₂ there was less difference between the seasons and the average enrichment factor

335   was 1.2 – 1.3 (Table 1). Taking the development of the cross-section area (Christiansen &

336   Jørgensen, 2018) during field campaigns into account and using the average wind speed ± one

337   standard deviation, it was estimated that the range of hourly CH_4 and CO_2 fluxes increased from

338   May to August (Table 2) despite lower average mole fractions. We note that our total estimate

339   uses several approximations. Notably, we assume constant wind speed of subglacial air and air

340   temperature across the seasonal variation in cross section of the ice cave. It was previously

341   estimated that the subglacial air velocity could reach up to 2 m s^{-1} (Christiansen & Jørgensen,

342   2018) and in this study we observed fluctuations of the wind speed in this range from 0.1 to 2.5

343   m s^{-1} (Figure S3) with an average speed of 0.8 m s^{-1} and a standard deviation of 0.28 m s^{-1}.

344   Improving the measurement of the subglacial air velocity is key for more accurate quantification

345   of gaseous flux estimates in the future.

346   The short-term (minute scale) variability of gCH_4 and gCO_2 was apparently influenced by

347   turbulent mixing with the more dilute atmosphere outside the cave. This was indicated during all

348   campaigns by rapidly fluctuating gCH_4 and gCO_2 mole fractions (Figure 2a-c) and increasing air

349   temperature and decreasing humidity of the subglacial air (Figure S3). However, for most of the

350   time, the relative humidity in the cave remained at 100% and air temperatures were low (below

351   0.5°C) whereas the outside temperatures were higher (diel variation between 1 - 12°C)

352   indicating an overall low degree of mixing. In particular, the longer-scale diurnal variability is

353   likely not caused by mixing with the outside atmosphere, but by the subglacial supply of trace

354   gases. This is supported by the fact that in August 2018 the subglacial air temperature varied in a

355   pattern that corresponded to the diurnal variation in melt water flow, with highest subglacial air

356   temperatures observed under maximum flow (Figure S3). Whether the higher subglacial air

357   temperature is caused by heat dissipation from frictional heating of the turbulent meltwater or

358   higher influx of relatively warmer surface water is unknown. However, we conclude that the

359   short-term variability of CO_2 and CH_4 mole fractions in the subglacial cave system is a direct

360   product of occational turbulent mixing at the interface between the ice cave and the atmosphere,

361   whereas the diurnal cycle of gCH_4 and gCO_2 and total net emission we observe (Fig. 2A-C) is

362   directly related to the flow of melt water and not the atmospheric conditions outside the cave.

363   *Table 2 Flux range estimates of CH_4 and CO_2 for the non-water filled cross section of the subglacial river outlet for the May*

367 3.2 Isotopic composition of subglacial CH_4 and CO_2

368 Figure 3 shows a dual isotope plot of the isotopic signatures (δ^{13}C-CH$_4$ and δ^2H-CH$_4$)
369 estimated from separated Keeling plots (Figure S4A-D), for gaseous CH_4 and the isotopic
370 composition of the dissolved CH_4. compared to measurements of δ^{13}C and δ^2H values of discrete
371 gas samples for ambient air. These estimates clearly indicate that dCH$_4$ and gCH$_4$ originate from
372 microbial acetate fermentation.

373 The δ^{13}C values of dCH$_4$ at PW1 were depleted compared to the atmosphere and varied
374 little during each campaign and between June and August campaigns, suggesting a similar source
375 over the melt season. The isotopic signature of gCH$_4$ was slightly enriched in both ^{13}C and ^{2}H
376 and more variable compared to δ^{13}C values for dCH$_4$ for most of the June and August (Figure 3,
377 Figure S4).

378 The isotopic signatures (δ^{13}C and δ^2H) of gCH$_4$ varied along a line (slopes $\approx$ 5 and 7.4
379 for June and August 2018 campaigns, respectively) that resembles an oxidation pattern (Figure
380 3) suggesting *in situ* transformation of the subglacial CH_4. This points to the presence of an
381 active biological system below the ice, but its importance for modifying CH_4 emission to the
382 atmosphere is still unknown. The slope is smaller than what has earlier been attributed to
383 oxidation of dCH$_4$ (a=8.6-9) (Burns et al., 2018; Etiope & Sherwood Lollar, 2013) and while this
384 indicates that oxidation of subglacial CH_4 takes place, the lower slope for gCH$_4$ we find suggests
385 additional isotope fractionation processes could impact the isotopic signature of gCH$_4$. Future
386 research will focus on understanding what drives the deviation between the isotopic signature of
387 gCH$_4$ and dCH$_4$ as it has implications for interpretation of the origin of subglacial CH_4.

Figure 3 Dual isotope plot of Keeling plot estimates of the isotope source signatures (δ^{13}C-CH$_4$ and δ^2H-CH$_4$) for gCH$_4$ (transparent symbols and white marker line) in June 2018 (circles) and August 2018 (diamonds). Standard errors of the estimate of isotopic signature (gCH$_4$) are shown as error bars. Isotopic composition (δ^{13}C-CH$_4$ and δ^2H-CH$_4$) of dCH$_4$ are shown in white symbols with black edge for June 2018 (circles) and August 2018 (diamonds) campaigns. Grey shaded areas modified after Whiticar (1999). For comparison, the δ^{13}C and δ^2H values of atmospheric CH$_4$ are shown with X's.

Further evidence of an active microbial transformation of the subglacial CH$_4$ and CO$_2$ emissions is provided by the relation between isotopic δ^{13}C signatures of dissolved and gaseous subglacial CH$_4$ and of gaseous subglacial CO$_2$ (Figure 4a & b). The difference (-6 to 22‰) between the δ^{13}C isotopic signatures of gCO$_2$ and gCH$_4$, suggests that a substantial proportion of the subglacial gCO$_2$ is derived from CH$_4$ oxidation in the subglacial environment (Whiticar, 1999). Using the Keeling plot approach for δ^{13}C of gCO$_2$ (Figure S5) shows that the samples group in the zone of CH$_4$ oxidation on the dual isotope plot (Figure 4b). This provides field experimental confirmation for subglacial CH$_4$ oxidation to CO$_2$ which in previous studies has only been inferred indirectly (Burns et al., 2018).

16

404 We also observed that less δ^{13}C-depleted gCO_2 corresponded to increasing gCO_2 mole

405 fractions (Figure 4a). This cannot be explained by the subglacial CO_2 originating only from CH_4

406 oxidation, which produces ^{13}C-depleted CO_2 and indicates that one or more additional and

407 isotopically heavier sources of CO_2 contribute to subglacial CO_2. Mixing of subglacial air with

408 isotopically heavier atmospheric CO_2 could in principle enrich the gCO_2 in ^{13}C (as we observed

409 for δ^{13}C-CH_4), but it cannot increase gCO_2 mole fractions above the ambient level (Figure 2a-c).

410 Instead, it is possible that the increasing mole fraction and ^{13}C-enrichment of gCO_2 could

411 be due to an increased proportion of gCO_2 (and dCO_2) originating from remineralized subglacial

412 organic carbon (Pain et al. 2020), as the export of dCO_2 from remineralization of organic carbon

413 in subglacial sediments must also be governed by melt flow and subsequent degassing into the

414 subglacial air. Subglacial dissolved organic carbon at this outlet (Andrews et al., 2018), a

415 possible substrate for both methanogenesis and remineralisation, was much more enriched (δ^{13}C-

416 DOC: -29.8 to -24‰) in ^{13}C than subglacial CH_4. Subglacial CO_2 that is originating from this

417 carbon pool should therefore have a higher δ^{13}C isotopic signature than the strongly ^{13}C-depleted

418 CO_2 originating from subglacial CH_4 oxidation.

419 We observed increasing CO_2/CH_4 ratios in the subglacial air from average values

420 between 5 and 10 in May 2019 to average values >80 in August 2018 (Figure S6). This shows

421 that the export and emission of CO_2 changes during the melt season relative to CH_4 (Figure 2a-c,

422 Table 2), which could be driven by increased CH_4 oxidation and/or remineralisation of organic

423 carbon. As the internal drainage system develops until maximum flow over the melt season, the

424 residence time of the subglacial melt water should increase when the melting decreases later in

425 the year. This longer residence time could enhance subglacial CH_4 oxidation and its contribution

426 to dCO_2, and limit the export and subsequent emission of subglacial CH_4 to the atmosphere.

427 Also, the expanding ablation zone over the melt season connects pockets of subglacial sediment

428 which could not only lead to increased mobilization of CH_4 (Lamarche-Gagnon et al., 2019) (and

429 hence oxidation), but also of remineralization of organic carbon to CO_2 (Kellerman et al., 2020;

430 Kohler et al., 2017). Oxygen availability in the anoxic subglacial environment limits both the

431 oxidation of subglacial CH_4 (Michaud et al., 2017) and remineralization. However, it is plausible

432 that oxygen is supplied to subglacial environments, both from melting of O_2-containing basal ice

433 or import of oxygenated surface melt water. We observed that the subglacial melt water at the

434 outlet was fully oxygenated to nearly 100% of the atmospheric equilibrium during the June 2018

435   campaign (data not shown) indicating conditions conducive for both processes to occur in the

436   subglacial environment at this site. An additional possible source of subglacial CO_2 could be

437   inorganic carbonate dissolution from the bedrock and the size of this contribution is determined

438   by the endogenous carbonate content of the bedrock and subglacial weathering rates.

439   Thus, several CO_2 generating processes likely occur simultaneously, and how they

440   contribute to the resulting net emission in the proglacial zone is closely connected to the glacial

441   hydrology and basal distribution of carbon containing sediment and bedrock of the catchment.

442   The interaction between these factors complicates the interpretation of δ^{13}C-CO_2 values and

443   future research should focus on partitioning the subglacial CO_2 sources (oxidation,

444   remineralization, dilution with atmospheric air, inorganic carbon from carbonate dissolution)

445   using both gCO_2 and dCO_2 together with measurements of subglacial CH_4. This source

446   identification should enable us to narrow in on where in the subglacial system, in transit with the

447   meltwater (Dieser et al., 2014; Lamarche-Gagnon et al., 2019) or at the ice-sediment interface at

448   the subglacial source (Burns et al., 2018; Michaud et al., 2017) the production and release of CO_2

449   happens.

450

458

459   **4 Conclusions**

460   In this study we present direct continuous measurements of gaseous evasion of CH_4 and

461   CO_2 from below the Greenland Ice sheet at three different stages of a melt season. These unique

462   seasonal measurements are supported by isotopic studies of both subglacial CH_4 and CO_2 in

463   discrete gas and water samples and show high emissions of CH_4 and CO_2 from the subglacial

464   environment to the atmosphere. Results show that degassing of dissolved gases happens both

465   under the ice in the subglacial cave system and in the proglacial river system confined to a

466   relatively narrow zone from the outlet.

467   Gaseous CH_4 and CO_2 emissions are closely linked to the glacial hydrology and

468   emissions from the outlet increase over the melt season related to the discharge and development

469   of the subglacial drainage system, allowing more degassing in the subglacial system later in the

470   season. The large emissions of CH_4 and CO_2 point to a significant contribution to the

471   atmosphere. Considering that the phenomenon should also occur at other glaciers along the

472   margin of GrIS and in Iceland, warrants intensified research.

473   The isotopic signatures show that subglacial CH_4 originates from biological production of

474   CH_4 by acetoclastic methanogenesis, likely from buried organic carbon, which is the source

475   throughout the melt season. Isotopic analysis also shows that the emitted subglacial CO_2 is

476   linked to oxidation of thissubglacial CH_4. However, the isotopic composition of subglacial CO_2

477   point to other possible sources of subglacial CO_2 apart from CH_4 oxidation and we suggest that

478   remineralisation of organic carbon also contributes to the emission of CO_2 at the outlet. The

479   proportion of CO_2 emission relative to CH_4 increases over the melt season possibly reflects

480   increased oxidation of CH_4 and remineralisation of organic carbon. This is likely fueled by a

481   combination of increased oxygen input from surface water and longer residence time of melt

482   water in the subglacial drainage system. However, it is still unknown where in the subglacial

483   system (sediment, melt water or both) the CH_4 oxidation takes place. The interpretation of the

484   isotope signals suggests that the emitted CH_4 and CO_2 undergo biogeochemical transformation

485   below the ice and that mixing or dilution with other sources during transport under the ice can

486   occur.

487   Our study shows that large amounts of biogenic CH_4 and CO_2 are emitted from the GrIS

488   via glacial meltwater. However, considerable uncertainty still exists, related to the quantification

489   of the exact mass flux of CH_4 and CO_2 due to an unknown partitioning between aqueous and

490   gaseous fluxes, as well as uncertainty of the measurement of physical parameters (e.g. wind

491   speed and direction) controlling the net emission. There is a need to advance the fundamental

492   knowledge of the emission of subglacial CO_2 and CH_4 and the biogeochemical processes

493   governing the production and turnover of subglacial carbon to understand this unknown carbon-

494   cryosphere feedback from glaciers and ice sheets worldwide and determine its importance for the

495   atmospheric composition of CH_4 and CO_2.

599 ***Captions***

600 **Figure 5** Top panel: Map of West Greenland and Isunnguata glacier with study site indicated at
601 red squares (top left inset) and an overview of the study site at the ice front in June 2018. Letters

602 (a, b, c) indicate location of measurement of mole fractions of CH_4 and CO_2 in subglacial air and
603 sampling of melt water at three different stages during the melt season. a) May 2019 represents
604 the early stage meltwater discharge where the meltwater openings are small and mostly filled
605 with water. b) June 2018 represents a progressive stage of opening where multiple cracks and
606 caves are air filled after the meltwater has carved out channels in the ice. c) August 2018
607 represents the mature stage of evolution of the meltwater channel, where the volume of the outlet
608 is at its maximum and most of it is air filled due to decreasing meltwater volumes.

609 **Figure 6** Upper panels (a-c): Time series of gaseous mole fractions of CH_4 (green) and CO_2
610 (grey) in a) June 2018, b) August 2018 and c) May 2019. Black dashed line indicates the
611 atmospheric mole fractions of CH_4 (2 ppm) and CO_2 (400 ppm) measured on site. Lower panels
612 (d-f): Dissolved CH_4 concentrations at three distances (● PW1: 0 m from outlet; ◆ PW2: 200 m
613 from the outlet; ▲ PW3: 2000 meter from the outlet) for d) June 2018, e) August 2018 and f)
614 May 2019. Black dashed line indicates the estimated dissolved concentration of CH_4 at
615 atmospheric equilibrium (0.02 μmol L^{-1}).

616 **Figure 7** Dual isotope plot of Keeling plot estimates of the isotope source signatures ($\delta^{13}C$-CH_4
617 and δ^2H-CH_4) for gCH_4 (transparent symbols and white marker line) in June 2018 (circles) and
618 August 2018 (diamonds). Standard errors of the estimate of isotopic signature (gCH_4) are shown
619 as error bars. Isotopic composition ($\delta^{13}C$-CH_4 and δ^2H-CH_4) of dCH_4 are shown in white
620 symbols with black edge for June 2018 (circles) and August 2018 (diamonds) campaigns. Grey
621 shaded areas modified after Whiticar (1999). For comparison to the isotopic composition of
622 dCH_4 and signature of gCH_4 the $\delta^{13}C$ and δ^2H values of atmospheric CH_4 are shown with X's.

623 **Figure 8** a) Temporal variation of isotopic ($\delta^{13}C$) source signatures for gaseous CO_2 (◇) and
624 CH_4 (●) and the isotopic composition of dissolved subglacial CH_4 (○). Subglacial gaseous CO_2
625 mole fractions (ppm) are superimposed as grey line. Vertical error bars for gCO_2 and gCH_4
626 indicate the standard error of the Keeling plot intercept; in most cases error bars were smaller
627 than the symbols. indicate the $\delta^{13}C$ values of atmospheric CO_2 (orange) and CH_4 (green),
628 respectively and b) Dual isotope plots showing the resulting Keeling plot isotope signature of
629 gCO_2 ($\delta^{13}C$-CO_2) plotted against the isotopic signature of gCH_4 (orange diamonds). Standard
630 errors of the Keeling plot intercept are shown as vertical and horizontal error bars. In most cases
631 error bars were smaller than the symbols.

632 **Table 3** Average, minimum and maximum gaseous subglacial CH_4 and CO_2 mole fractions in
633 May 2019, June 2018 and August 2018 campaigns. *The enrichment factor (xAtmosphere)
634 relative to the atmosphere for CH_4 and CO_2 is based on in situ measurements of the atmospheric
635 molefractions of CH_4 = 2 ppm and CO_2= 400 ppm.

636 **Table 4** Emission range estimates of CH_4 and CO_2 for the non-water filled cross section of the
637 subglacial river outlet for the May 2019, June 2018 and August 2018 campaigns.
