

## Abstract

The observed partitioning of poleward heat transport between atmospheric and oceanic heat transports (AHT and OHT) is compared to that in coupled climate models. Poleward OHT in the models is biased low in both hemispheres, with the largest biases in the Southern Hemisphere extratropics. Poleward AHT is biased high in the Northern Hemisphere, especially in the vicinity of the peak AHT near 40°N. The significant model biases are persistent across three model generations (CMIP3, CMIP5, CMIP6) and are insensitive to the satellite radiation and atmospheric reanalyses products used to derive observational estimates of AHT and OHT. Model biases in heat transport partitioning are consistent with biases in the spatial structure of energy input to the ocean and atmosphere. Specifically, larger than observed model evaporation in the tropics adds excess energy to the atmosphere that drives enhanced poleward AHT at the expense of weaker OHT.

## Plain Language Summary

The equator-to-pole contrast of solar radiation entering the climate system drives the large-scale oceanic and atmospheric circulations that, in turn, move heat from the equator to the poles to moderate latitudinal temperature contrasts. The ocean moves the majority of heat in the tropics whereas the atmosphere moves the vast majority of heat in the mid- and polar-latitudes. We demonstrate that state-of-the-art climate models representing both oceanic and atmospheric circulations systematically simulate too little oceanic heat transport and too much atmospheric heat transport relative to observational estimates. These model biases in the atmosphere-ocean partitioning of poleward heat transport are persistent across three generations of climate model ensembles spanning twenty years of progress in climate modeling and are insensitive to the choice of datasets used to calculate observed heat transports. The model biases are consistent with stronger than observed surface evaporation in the tropics which enhances atmospheric heat transport at the expense of oceanic heat transport.

## 1 Introduction

The combined meridional heat transport (MHT) by the ocean and atmosphere moderates spatial gradients in temperature on Earth. In the absence of MHT, the equator-to-pole temperature gradient would be approximately three times larger than observed based on radiative considerations alone (Pierrehumbert, 2010), rendering the tropics uninhabitably warm and the high latitudes uninhabitably cold. Observational estimates of the partitioning of MHT between poleward atmospheric heat transport (AHT) and poleward oceanic heat transport (OHT) show that OHT exceeds AHT in the deep tropics (equatorward of 10°) while AHT dominates in the mid- and high-latitudes of both hemispheres (Vonder Haar & Oort, 1973; Oort & Haar, 1976; Trenberth & Caron, 2001; Mayer et al., 2021).

The partitioning of MHT between AHT and OHT impacts climate and its changes. For example, the convergence of OHT in the extratropics is inherently linked to the surface energy budget and thus demands a surface temperature response, whereas the convergence of the same quantity of AHT in the atmosphere can be radiated to space with less impact on surface climate (Cardinale et al., 2020). Indeed, previous work by Enderton & Marshall (2009) has shown that aquaplanets with nearly identical total MHT but different AHT-OHT partitioning can have very different climates (e.g., different surface temperature and sea ice distributions).

Given the dependence of climate on the partitioning between poleward AHT and OHT, we ask here: how well do coupled climate models represent the observed AHT-OHT partitioning? This question was briefly addressed in Chapter 9 of the Intergovern-

69 mental Panel on Climate Change 5th assessment report (Flato et al., 2013) which con-  
 70 cluded that model OHT was within the wide range of observational OHT estimates. Com-  
 71 parison of observational and model AHT-OHT partitioning is difficult because the stan-  
 72 dard methodology for partitioning MHT between AHT and OHT differs between obser-  
 73 vations and models due to the contrasting reliability and availability of the climate fields  
 74 used to calculate AHT and OHT. Recent work (Donohoe et al., 2020) has demonstrated  
 75 the near equivalence of the model and observational approaches to AHT-OHT partition-  
 76 ing in a model setting, enabling a comprehensive observational-model comparison. In  
 77 this study we apply these methods to three generations of coupled model simulations (Phases  
 78 3, 5, and 6 of the Coupled Model Intercomparison Project, CMIP) and to several obser-  
 79 vational radiation and atmospheric reanalysis products. Our aim is to determine whether  
 80 the models accurately capture the partitioning of AHT and OHT derived from obser-  
 81 vational datasets.

82 In Section 2 we provide an overview of the observational and model methodologies  
 83 for partitioning MHT into AHT and OHT and demonstrate the near equivalence of these  
 84 two approaches. In section 3, we compare the observational and model MHT partition-  
 85 ing across the three different model generations (CMIP3, CMIP5, and CMIP6) and ex-  
 86 amine the sensitivity of our findings to the choice of observational data sets used to par-  
 87 tition MHT. In Section 4 we consider an alternative method for comparing AHT-OHT  
 88 partitioning in models and observations from the processes that contribute to spatial gra-  
 89 dients in energy input to the atmosphere and ocean. A summary and discussion follows.

## 90 2 Methods for partitioning MHT into AHT and OHT in observations 91 and coupled models

92 The methodology used to partition MHT into AHT and OHT in coupled climate  
 93 models and observations is described in detail in Donohoe et al. (2020). Here we sum-  
 94 marize the conceptual approach.

### 95 2.1 Heat transport partitioning in climate models

96 Near closure of the top of atmosphere (TOA) and surface energy budgets in climate  
 97 models allows for the energy transport by the atmosphere and ocean across a latitude  
 98 band to be calculated from the energy input into/out-of the fluid spatially integrated over  
 99 the polar cap bounded by that latitude:

$$100 \text{MHT}(\Theta) = 2\pi a^2 \int_{\Theta}^{90} -F^* \cos \theta d\theta, \quad (1)$$

101 where  $a$  is the radius of the Earth,  $\Theta$  is the latitude (with  $\theta$  a latitude variable of inte-  
 102 gration), and  $F$  is the net energy input to the atmosphere, ocean, or combined atmosphere-  
 103 ocean system. The total MHT can be found by taking  $F$  to be the radiative flux at the  
 104 TOA ( $\text{RAD}_{\text{TOA}}$ ), OHT by taking  $F$  to be the net surface heat flux ( $\text{SHF} = \text{radiative}$   
 105  $\text{plus turbulent flux into the ocean}$ ), and AHT by setting  $F$  to be the net energy input  
 106 to the atmosphere ( $\text{RAD}_{\text{TOA}} - \text{SHF}$ ). The \* denotes that the global mean of each en-  
 107 ergy flux term has been removed to ensure heat transport goes to zero at both poles. This  
 108 adjustment is necessary because climate models do not conserve energy globally ( $\approx 1 \text{ W}$   
 $\text{m}^{-2}$  imbalances) in both the atmosphere and ocean (Lucarini & Ragone, 2011).

### 109 2.2 Heat transport partitioning in observations

110 In contrast to coupled climate models where the surface energy budget is (nearly)  
 111 closed, the sparsity and uncertainty of observational surface radiative and turbulent en-  
 112 ergy flux measurements results in an unrealistically large ( $>10 \text{ W m}^{-2}$ ) global mean sur-

113 face energy imbalance (Stephens et al., 2012; Trenberth et al., 2009), which prohibits the  
 114 evaluation of OHT from the net surface heat flux. Instead, we use a conceptual approach  
 115 following Vonder Haar & Oort (1973) and Trenberth & Caron (2001): MHT is calculated  
 116 using Eq. 1 with satellite  $\text{RAD}_{\text{TOA}}$  (Loeb & Coauthors, 2018); AHT is calculated from  
 117 the time average of the vertically and zonally integrated meridional energy flux in the  
 118 atmosphere derived from high frequency (6 hourly) atmospheric reanalysis; OHT is then  
 119 calculated as the residual of satellite derived MHT and reanalysis derived AHT. In the  
 120 AHT calculation, a vertically integrated moist static energy anomaly is removed before  
 121 integrating (Donohoe & Battisti, 2013; Cardinale et al., 2020; Donohoe et al., 2020), ef-  
 122 fectively applying a mass correction needed to make the AHT calculation physically mean-  
 123 ingful (Trenberth & Stepaniak, 2003; Liang et al., 2018).

124 To show that the "observational" and "model" methods are comparable, we parti-  
 125 tion MHT into AHT and OHT using both methods in a NCAR CESM1 coupled pre-  
 126 industrial control simulation (see Donohoe et al., 2020, for details). The two approaches  
 127 give nearly identical partitioning of MHT into AHT and OHT (cf. the dashed and solid  
 128 red and blue lines in Supporting Information Fig. S1) with a root mean squared differ-  
 129 ence AHT (and OHT) between the two methods of 0.07 PW. The close correspondence  
 130 of the two calculations of MHT partitioning suggests that the "observational" and "model"  
 131 approaches we use here to partition MHT are directly comparable. We use this result  
 132 to justify the examination of potential model biases in MHT partitioning using these two  
 133 methodologies.

### 134 3 Results: model biases in MHT partitioning

135 Climate model biases in MHT partitioning are analyzed using pre-industrial control  
 136 simulations from three different CMIP generations and several different sets of ob-  
 137 servational products (see Supporting Information for details). The presentation of our  
 138 results is organized as follows. Section 3.1 presents the observational estimate of MHT  
 139 partitioning using the most contemporary and high resolution data available, which is  
 140 compared against the MHT partitioning in the three CMIP ensembles. Section 3.2 an-  
 141 alyzes the sensitivity of our results to the observational data used by comparing eight  
 142 different observational estimates of MHT partitioning against the multi-generation CMIP  
 143 ensemble mean. The results show that the sign and spatial structure of model biases in  
 144 MHT partitioning are consistent across model generation and observational data sets used.

#### 145 3.1 Consistent model biases in AHT-OHT partitioning across three CMIP 146 generations

147 In this section, we use CERES Energy Balanced and Filled (EBAF) TOA radia-  
 148 tion (Loeb et al., 2009) and the ERA5 atmospheric reanalysis (Hersbach et al., 2020) to  
 149 calculate an observational estimate of MHT and its partitioning over the period 2001-  
 150 2020. This observational estimate (solid line) is compared against each of the three CMIP  
 151 ensembles (in each row of Fig. 1; with dashed lines showing individual models and the  
 152 thick dashed lines showing CMIP ensemble averages).

153 Poleward MHT peaks near  $35^\circ$  in both hemispheres in both models and observa-  
 154 tions (Fig. 1), consistent with constraints due to Earth-Sun geometry whereby the merid-  
 155 ional distribution of net TOA radiation ( $\text{RAD}_{\text{TOA}}^*$ ) is dominated by the second order Leg-  
 156 endre polynomial (equator-to-pole scale) as discussed by Stone (1978). However, across  
 157 all three CMIP generations, the amplitude of poleward MHT in models is biased low in  
 158 the mid-latitudes of both hemispheres relative to the observational estimate. In the South-  
 159 ern Hemisphere (SH), the observational estimate of maximum poleward MHT is 5.7 PW,  
 160 which is significantly larger (95% confidence interval of t-test) than the ensemble means  
 161 of CMIP3 (5.2 PW), CMIP5 (5.3 PW), and CMIP6 (5.4 PW). In the Northern Hemi-  
 162 sphere (NH) the observational estimate of maximum poleward MHT is 5.8 PW, exceed-

163 ing the ensemble mean of CMIP3 (5.6 PW), CMIP5 (5.5 PW), and CMIP6 (5.7 PW),  
 164 but only for CMIP5 is the difference statistically significant. In the SH, the inter-model  
 165 spread in peak MHT (2 standard deviations) is as large as 23% of the ensemble mean  
 166 and has values of 1.2 PW in CMIP3, 0.8 PW in CMIP5, and 0.8 PW in CMIP6. The  
 167 inter-model spread in peak NH MHT is smaller than its SH counterpart with values of  
 168 0.8 PW in CMIP3, 0.6 PW in CMIP5, and 0.6 PW in CMIP6. Donohoe & Battisti (2011)  
 169 demonstrated that the the inter-model spread and bias in MHT in CMIP3 results from  
 170 biases and spread in the albedo of clouds which impact the equator-to-pole gradient of  
 171 absorbed solar radiation. The bias and spread in MHT is only slightly reduced in CMIP5  
 172 and CMIP6, and also results primarily from model differences in mean-state shortwave  
 173 cloud radiative effects (not shown).

174 We next analyze the partitioning of MHT between OHT and AHT. In the NH, the  
 175 model ensemble mean is significantly biased toward too little poleward OHT and too much  
 176 poleward AHT in all three CMIP generations. The observational estimate of peak NH  
 177 AHT is 4.4 PW as compared to  $4.7 \pm 0.2$  PW in CMIP3,  $4.7 \pm 0.1$  PW in CMIP5, and  
 178  $4.8 \pm 0.1$  PW in CMIP6 where the stated uncertainty is two standard deviations of the  
 179 ensemble mean. The peak in NH OHT is robustly equatorward of the peak AHT, but  
 180 has significantly larger values for the observational estimate (2.0 PW) than in the model  
 181 ensemble means (1.7 PW in CMIP3, 1.8 PW in CMIP5, and 1.7 PW in CMIP6). The  
 182 model bias toward smaller than observed OHT extends poleward to the Arctic where OHT  
 183 has been demonstrated to have large impacts on sea ice extent (Holland et al., 2006; Sea-  
 184 ger et al., 2002).

185 In the SH, poleward OHT in the models is biased low relative to the observational  
 186 estimate in all three CMIP generations. The largest biases in OHT are found the vicinity  
 187 of  $40^\circ\text{S}$  where the observational OHT is -0.7 PW compared to the ensemble mean  
 188 OHT at that latitude is  $-0.3 \pm 0.2$  PW in CMIP3,  $-0.2 \pm 0.1$  PW in CMIP5, and  $-0.1$   
 189  $\pm 0.1$  PW in CMIP6. The observational estimate of poleward OHT is only exceeded in  
 190 three model simulations (two in CMIP3 and one in CMIP5). In contrast, the poleward  
 191 AHT in the SH is not significantly different between the models and observational es-  
 192 timates.

193 These results suggest that in the SH, the majority of the model biases in MHT are  
 194 a result in biases in OHT, whereas in the NH the models generally simulate too much  
 195 poleward AHT and too little poleward OHT. Alternatively, the fractional contribution  
 196 of AHT-OHT to total MHT (i.e., normalizing each model by the model specific MHT)  
 197 is biased toward too much poleward AHT and too little poleward OHT with biases that  
 198 are nearly hemispherically symmetric between the two hemispheres (not shown). Import-  
 199 tantly, the sign and spatial structure of model biases in MHT and AHT-OHT partition-  
 200 ing are remarkably consistent across the three CMIP generations spanning over 20 years  
 201 of progress in climate modeling.

### 202 **3.2 Sensitivity of results to observational data sets used**

203 We next consider whether the identified model biases in AHT-OHT partitioning  
 204 are sensitive to the choice of observational data sets (TOA radiation and atmospheric  
 205 reanalysis) used to partition MHT. We use the mean of all ensemble members across all  
 206 three CMIP generations, referred to as the CMIP-mean, as a reference for all analyses  
 207 in this subsection.

208 We begin by analyzing the MHT and AHT/OHT partitioning estimated using two  
 209 additional satellite-derived observational estimates of TOA radiation (see Supporting In-  
 210 formation for details): the unadjusted CERES single scanner footprint (SSF) data and  
 211 the ERBE satellite data which spans the 1984-1990 (left panels of Fig. 2 bordered by  
 212 the black box). In these three panels, the choice of TOA radiation product alters the cal-  
 213 culated observational MHT (solid black line) whereas the AHT is unchanged between

panels (ERA5 is used in each). Because the observational OHT is calculated from the difference of MHT and AHT, the observational OHT estimate (solid blue line) also varies between panels. Observational MHT calculated from the three different TOA radiation products is consistently larger than the CMIP-mean in both hemispheres. Model biases in MHT are largest when the CERES SSF product is used (Fig. 2E) and smallest when the ERBE product is used (Fig. 2C). The CMIP-mean OHT is biased low compared to that derived from all three TOA radiation datasets with largest magnitude biases when CERES SSF is used, especially in the SH. Model biases in AHT/OHT partitioning are insensitive to observational TOA radiation data set used which give a consistent estimate of MHT despite their substantial ( $\approx 5 \text{ W m}^{-2} = 2.5 \text{ PW}$  globally integrated) differences in global mean TOA radiative balance associated with absolute calibration uncertainty (Loeb et al., 2009).

We next analyze the sensitivity of our results to the choice of atmospheric reanalysis used to calculate the AHT (Fig. 2 panels A, B, D, F and H). In these five panels, the MHT is identical (calculated using the CERES EBAF product) whereas the AHT is calculated from the ERA5, ERA-interim, NCEP, MERRA2, and JRA reanalyses. Since OHT is calculated from the residual of MHT and AHT, the OHT difference between the three panels are equal and opposite to the the inter-panel differences in AHT. The CMIP-mean bias toward too much poleward AHT and too little poleward OHT is apparent using all five observational estimates of AHT. Poleward AHT is largest when using ERA5 followed closely by JRA, MERRA2 and then ERA interim, whereas using NCEP produces the smallest poleward AHT with the most notable difference near the peak in the SH at  $40^\circ\text{S}$ . Therefore, model biases in the AHT-OHT partitioning are smallest using ERA5 and largest using NCEP. These results suggest that the sign and spatial structure of model biases in MHT partitioning are consistent across atmospheric reanalysis datasets, whereas the magnitude of the bias depends on the reanalyses product used. Differences in AHT calculated between the different reanalyses are not impacted by differences in the spatial resolution (see analysis and Fig. S2 in the Supporting Information) as even the coarsest product (NCEP) resolves the spatial scales responsible for the vast majority of AHT.

Finally, we evaluate whether heat storage due to the transient response to anthropogenic forcing impacts our observational estimates of OHT. The Earth is not in equilibrium but, rather, is accumulating energy at an average rate of  $0.7 \text{ W m}^{-2}$  globally (Johnson et al., 2016). The vast majority of this energy accumulation is stored in the ocean (Von Schuckmann et al., 2016) and it is possible that the spatial structure of this energy storage projects onto our diagnoses of observational OHT for the following reason: observed ‘implied’ OHT is calculated from the spatial integral of inferred surface heat fluxes (TOA radiation plus AHT convergence) and the latter is balanced by the sum of OHT divergence and ocean heat storage in a transient system. We diagnose the impact of observed ocean heat storage on the implied OHT ( $\text{OHT}_{\text{STORAGE}}$ ) from the trend in ocean heat content, derived from UK Hadley Center EN4 objective ocean analysis (Good et al., 2013) over the CERES period (see Supporting Information for details).  $\text{OHT}_{\text{STORAGE}}$  is removed from the ‘implied’ OHT to estimate the ‘true’ OHT (solid teal line in Fig. 1F) that must be transported laterally in the ocean to close the ocean energy budget.  $\text{OHT}_{\text{STORAGE}}$  is very small ( $< 0.1 \text{ PW}$  in magnitude) and, thus, the diagnosed ‘true’ OHT is visually indistinguishable from the observational ‘implied’ OHT (solid blue line in Fig. 1F). The global mean ocean heat uptake of  $0.7 \text{ W m}^{-2}$  translates to  $0.4 \text{ PW}$  of global energy input to the ocean but the implied OHT of ocean heat storage is significantly smaller in magnitudes due to ocean heat uptake being more globally uniform than regionally isolated. The negligible impact of ocean heat storage on ‘implied’ OHT over the historical period is consistent with the small ( $< 0.1 \text{ PW}$ ) differences between OHT in the ensemble mean of historical CMIP5 simulations averaged over the 2000-2018 time period as compared the pre-industrial control simulations using the same models (Supporting Information Fig. S3).

268 Collectively, these results suggest that the sign of model biases in AHT-OHT par-  
 269 titioning is robust to different observational products (satellite TOA radiation and at-  
 270 mospheric reanalysis) used to partition MHT. Additionally, the spatial pattern of tran-  
 271 sient heat uptake by the ocean makes a negligible impact on estimated OHT. However,  
 272 the magnitude of the model bias in AHT-OHT partitioning does vary with observational  
 273 datasets used. In this regard, the use of CERES EBAF and ERA5 data for our primary  
 274 analysis (Fig. 1) is a conservative estimate of model biases in AHT-OHT partitioning  
 275 (a smaller OHT bias is found only when using the combination of ERBE and ERA5 prod-  
 276 ucts).

#### 277 4 Biases in energy input to the atmosphere and ocean and inferred AHT 278 and OHT biases

279 Here we evaluate potential causes of the persistent model biases in AHT and OHT  
 280 in terms of model biases in the spatial structure of energy input into the ocean and at-  
 281 mosphere. Starting in the ocean, energy conservation demands that OHT across a lat-  
 282 itude band balances the net surface heat flux *out* of the ocean (-SHF by our sign con-  
 283 vention) integrated over the polar cap bounded by that latitude, which from Eq. 1 is rep-  
 284 resented by:

$$\text{OHT}(\Theta) = 2\pi a^2 \int_{\Theta}^{90} (-\text{SHF}^*) \cos(\theta) d\theta. \quad (2)$$

285 SHF is equal to the net downward surface radiation ( $\text{RAD}_{\text{SURF}}$ ) into the ocean minus  
 286 the upward turbulent energy fluxes of sensible (SENS) and latent heat ( $L_v E$ ):

$$\text{SHF} = \text{RAD}_{\text{SURF}} - \text{SENS} - L_v E. \quad (3)$$

287 Substitution of Eq. (3) into Eq. (2) allows the OHT to be decomposed into the implied  
 288 transports of each term contributing to SHF:

$$\text{OHT} = \text{OHT}_{\text{RAD,SURF}} + \text{OHT}_{\text{SENS}} + \text{OHT}_E, \quad (4)$$

289 where, for example, the OHT implied by evaporation ( $\text{OHT}_E$ ) is:

$$\text{OHT}(\Theta)_E = 2\pi a^2 \int_{\Theta}^{90} L_v E^* \cos(\theta) d\theta, \quad (5)$$

290 where, as in Eq. 1 and 2, the \* indicates that the global (ocean domain) mean has been  
 291 removed from the term. Because  $\text{SENS}^*$  is small compared to the other terms (Fig. 3C)  
 292 and  $\text{RAD}_{\text{SURF}}$  is dominated by solar input to the surface (Supporting Information Figs.  
 293 S5E,F), the predominant energy balance in this framework can be summarized as fol-  
 294 lows: the magnitude of OHT (black line in Fig. 3D) is governed by the imbalance be-  
 295 tween excess (relative to the global mean) solar radiation entering the tropical ocean (or-  
 296 ange line) and excess evaporative loss (green). Perfect local compensation between sur-  
 297 face solar input and evaporation implies zero OHT whereas weaker evaporative loss de-  
 298 mands a larger fraction of solar input be realized as OHT. We use this framework to un-  
 299 derstand model biases in OHT in terms of biases in the meridional structure of terms  
 300 contributing to SHF.

301 The latitudinal structure of CMIP-mean  $L_v E$ , SENS and  $\text{SURF}_{\text{RAD}}$  over the ocean  
 302 domain is compared to observational estimates of the same quantities with  $L_v E$  and SENS  
 303 taken from the WHOI Objectively Analyzed (OA) Air-Sea Flux product (Yu et al., 2004)  
 304 and  $\text{SURF}_{\text{RAD}}$  estimates from the CERES EBAF surface product (Kato & Coauthors,

2018) in Fig. 3C. Evaporation is biased high in models (relative to the observational estimate) at all latitudes except the Arctic (Supporting Information Fig. S4). Evaporation biases are largest ( $> 20 \text{ W m}^{-2}$ ) in the subtropics of both hemispheres and are much smaller in the high latitudes. These evaporation biases manifest as enhanced subtropical ocean energy loss by  $E^*$  in the models (cf. the dashed and solid green lines in Fig. 3C) and an implied model bias toward too little (by approximately 0.4 PW) poleward OHT due to evaporation in each hemisphere ( $\text{OHT}_E$ , green line in Fig. 3D). Thus, evaporation biases alone explain the majority of the model bias in OHT identified in Section 3 (compare green and dashed black lines in Fig. 3D).

The observational  $\text{RAD}_{\text{SURF}}^*$  has a stronger equator-to-pole gradient than that in climate models (cf. the solid and dashed orange lines in Fig. 3C) especially in the SH. Model biases in  $\text{RAD}_{\text{SURF}}^*$  are associated with larger than observed downwelling solar radiation into the extratropical Southern Ocean (Supporting Information Fig. S5E) due to clouds that are optically thinner than observed (Donohoe & Battisti, 2012). As a result, observed poleward  $\text{OHT}_{\text{RAD,SURF}}$  is larger than that in models with larger magnitude (0.4 PW) biases in the SH. The model biases in  $\text{OHT}_{\text{RAD,SURF}}$  mirror the impact of TOA radiation biases on MHT (left panels of Figure 1) including the partitioning between shortwave and longwave biases within each hemisphere, suggesting that model biases in MHT and OHT in the SH are due to biases in shortwave absorption whereas those in the NH are due to biases in OLR and net surface longwave (Supporting Information Figs. S5B,F).

The sum of model biases in  $\text{OHT}_E$ ,  $\text{OHT}_{\text{RAD,SURF}}$  and  $\text{OHT}_{\text{SENS}}$  (solid black line in Fig. 3D) finds that models would have weaker than observed poleward OHT of 0.6 PW in the NH and 0.8 PW in the SH based on biases in energy input to the ocean. This overall inferred OHT bias is primarily due to a nearly hemispherically mirror-imaged bias in  $\text{OHT}_E$  which is enhanced by poleward  $\text{OHT}_{\text{RAD,SURF}}$  in the SH. The bias in OHT inferred from surface flux biases matches the spatial structure but exceeds in magnitude the OHT biases calculated in Section 3 from TOA radiation and atmospheric reanalysis (dashed black line in Fig. 3D). These two calculations of model OHT biases do not have to match as they use different conceptual approaches and rely on completely independent observational climate fields. Nonetheless, the consistency of the sign, spatial pattern, and magnitude of the OHT biases calculated using the two different approaches suggest that the model biases in surface energy fluxes are large enough to account for the AHT-OHT partitioning biases inferred from the residual TOA radiation and AHT estimates.

We use a similar calculation of the model biases in implied AHT from the spatial structure of energy input to the atmosphere to compute an alternative estimate of AHT biases to those calculated in Section 3. The AHT analog to Eq. 4 is:

$$\text{AHT} = \text{AHT}_{\text{RAD,ATMOS}} + \text{AHT}_{\text{SENS}} + \text{AHT}_E, \quad (6)$$

where the atmospheric analog to Eq. 5 for the AHT due to evaporation ( $\text{AHT}_E$ ) is:

$$\text{AHT}(\Theta)_E = 2\pi a^2 \int_{\Theta}^{90} -L_v E^* \cos(\theta) d\theta. \quad (7)$$

The spatial integral is over a global (land plus ocean) domain. Here  $\text{RAD}_{\text{ATMOS}}$  is the net radiative heating of the atmospheric column which is equivalent to the net radiation at TOA minus  $\text{RAD}_{\text{SURF}}$ . Fajber et al. (2023) demonstrated that poleward AHT is primarily determined by evaporation ( $\text{AHT} \approx \text{AHT}_E$ ) because  $L_v E^*$  dominates the spatial structure of energy input to the atmosphere. We note that  $L_v E^*$  spatially integrated over the ocean domain has opposing impacts on  $\text{AHT}_E$  versus  $\text{OHT}_E$  (and likewise for  $\text{SENS}^*$  and  $\text{AHT}_{\text{SENS}}$  versus  $\text{OHT}_{\text{SENS}}$ ). This arises because excess evaporation over the

low latitudes ( $E^* > 0$ ) adds energy to the atmosphere to enhance the demand for poleward AHT at the expense of removing energy from the low-latitude ocean to reduce the demand for poleward OHT.

To more clearly see the compensation between biases in AHT-OHT due to model biases in  $L_V E^*$  (and  $SENS^*$ ) over the ocean domain, we take the following approach to compare models and observations of AHT via Eqs. 6 and 7. First,  $AHT_E$  and  $AHT_{SENS}$  are calculated from the observational WHOI OA evaporation and sensible heat flux data *over the ocean domain only*, and are compared to analogous model calculations over the ocean domain. Then, the contribution of turbulent energy fluxes over land to the combined  $AHT_E$  and  $AHT_{SENS}$  is estimated from the CERES EBAF net surface radiation spatially integrated over land. This approach assumes that (via surface energy balance) surface radiative gain is balanced by turbulent loss. These calculations are compared to analogous calculations in the models. Finally,  $AHT_{RAD,ATMOS}$  is calculated from the CERES EBAF TOA and surface data *over the global domain* and is compared to the analogous global domain calculation in models (orange lines in Fig. 3A,B). This strategy circumvents the lack of reliable observational estimates of turbulent energy fluxes over land – instead inferring them from a like-with-like observational-to-model comparison of surface radiation over land and assuming that  $RAD_{SURF}$  is balanced by upward turbulent fluxes from the land to the atmosphere (the latter assumption has been validated in models).

Model biases in  $AHT_E$  compose the vast majority of AHT biases diagnosed from Eq. 6 (cf. the green and solid black lines in Fig. 3B) and suggest that the stronger than observed poleward AHT in models is driven by an enhanced equator-to-pole gradient in evaporation. Model  $RAD_{ATMOS}^*$  is more negative in the deep tropics as compared to observations (due to stronger longwave cooling in the models– Supporting Information Fig. S5) which contributes to smaller  $AHT_{RAD,ATMOS}$  export from the tropics in the models that generally opposes the low latitude biases in  $AHT_E$  (orange line in Fig. 3B). Interestingly, shortwave absorption in the atmosphere is biased low in the models, which reduces the demand for poleward AHT by nearly 0.4 PW in both hemispheres (red line in Supporting Information Fig. S5D). However, this model deficit in atmospheric heating of the tropics is nearly compensated for by weaker than observed longwave cooling of the atmosphere such that there is almost no bias in  $AHT_{RAD,ATMOS}$  at the equator-to-pole scale. Turbulent energy fluxes over the land inferred from net surface radiation are nearly identical in models and observations and make a negligible impact on AHT biases (cf. purple dashed and solid lines in Fig. 3C,D).

These calculations demonstrate that the model biases in the partitioning of poleward heat transport between AHT and OHT that were inferred in Section 3 are consistent (in sign, spatial structure, and magnitude) with the model biases in energy input into the atmosphere and ocean by radiative fluxes and turbulent exchange between the atmosphere and ocean. Stronger than observed evaporation in the models contributes to enhanced poleward AHT at the expense of reduced OHT that is nearly hemispherically symmetric whereas radiative biases due to thinner than observed clouds in the extratropical Southern Ocean results in too weak poleward MHT that is primarily manifested in the surface energy budget and implied OHT bias.

## 5 Summary and discussion

Coupled climate models have too little poleward OHT in both hemispheres and too much AHT in the NH, compared to observational estimates. These model biases are remarkably consistent across three generations of coupled model ensembles (CMIP3, CMIP5, and CMIP6) and across different sets of observational TOA radiation and atmospheric reanalysis data. These conclusions are not impacted by observed transient energy accumulation in the ocean.

402 The method used here to balance the mass budget of the atmospheric reanalysis  
 403 differs from that used in the work of Trenberth & Stepaniak (2004) and M. et al. (2017).  
 404 Specifically, we implicitly assume zero net atmospheric mass flux through a given lat-  
 405 itude circle whereas other works adjust the mass flux to balance the polar cap spatial  
 406 integral of the surface pressure tendency and evaporation minus precipitation. Our choice  
 407 stems from defining the energy budget with respect to a fixed mass of atmosphere (Dono-  
 408 hoe & Battisti, 2013; Liang et al., 2018). The AHT associated with the mass flux due  
 409 to evaporation minus precipitation is primarily compensated for a return flow of mass  
 410 and energy in the ocean and requires a consistent treatment of the energy fluxes through  
 411 the atmosphere, surface and ocean (M. et al., 2017) that depends on the choice of zero  
 412 point energy (e.g., the units used for temperature). Physically, a poleward (water) mass  
 413 flux in the atmosphere is balanced by the mass flux of precipitation minus evaporation  
 414 and an equivalent equatorward mass flux in the ocean. The energy flux of each of these  
 415 mass fluxes is the product of mass flux and mean energy of the fluid, has a minimal net  
 416 (AHT+OHT) poleward energy transport but is of order 0.2 PW in magnitude for each  
 417 the compensating AHT and OHT. The standard definition of SHF in climate models does  
 418 not include the sensible heat of this net (water) mass flux across the air/sea interface  
 419 and we believe including this term would create an inconsistency between the model de-  
 420 rived and observationally inferred OHT. Our interpretation is supported by the near equiv-  
 421 alence of the AHT calculated in CESM via the "observational" and "model" partition-  
 422 ing calculations using our method of calculating AHT from reanalysis data whereas in-  
 423 cluding the net mass flux of water in the AHT creates a substantial mismatch between  
 424 the two calculations (not shown). We emphasize that all choices made here were aimed  
 425 at creating a consistent way to compare observational and model MHT and AHT-OHT  
 426 partitioning despite the different climate fields that go into each calculation.

427 This work focused on model biases in the vertical zonal and time integral of atmo-  
 428 spheric moist static energy fluxes that comprise AHT without regard for biases in the  
 429 underlying atmospheric circulations and associated temperature and humidity structures  
 430 of the atmosphere. Donohoe et al. (2020) demonstrated that model biases in poleward  
 431 AHT primarily result from larger than observed dry (sensible) heat transport by tran-  
 432 sient eddies in the mid-latitudes of both hemisphere (their Fig. 4D) and in the NH smaller  
 433 than observed dry heat transport by stationary eddies; the moisture (latent heat) trans-  
 434 port has negligible biases. Model biases in evaporation are expected to be manifested  
 435 as biases in both moist and dry AHT because dry AHT is set by the spatial pattern of  
 436 condensational heating of the atmosphere which represents the portion of  $AHT_E$  that  
 437 is not transported poleward as latent heat (Fajber et al., 2023); while spatial patterns  
 438 of evaporation directly demand poleward moist AHT, the energy input to the atmosphere  
 439 via evaporation is handed off to dry AHT where precipitation forms and the atmosphere  
 440 is heated condensationally. Therefore, our finding that model biases toward too much  
 441 AHT result from stronger than observed evaporation is consistent with the finding that  
 442 excess poleward AHT in the models is expressed as a bias toward too much dry heat trans-  
 443 port.

444 Remarkably, the model OHT bias inferred from observational estimates from satel-  
 445 lite TOA radiation and atmospheric reanalyses is in descent agreement with model bi-  
 446 ases in the energy exchange between the ocean and atmosphere calculated from inde-  
 447 pendent observational estimates of surface heat fluxes. The latter bias is due primarily  
 448 to stronger than observed low-latitude evaporation in the models. We note that the com-  
 449 munity has been reluctant to diagnose OHT from the observed surface energy balance  
 450 because of uncertainty in the turbulent energy fluxes. Yet, our analysis paints a consis-  
 451 tent picture of the model biases in turbulent energy fluxes – whether these are inferred  
 452 from the residual of TOA radiation and AHT or from bulk formula. We also note that  
 453 observational estimates of global mean evaporation and its equator-to-pole gradient vary  
 454 substantially (Stephens et al., 2012) with reanalysis products generally having more evap-  
 455 oration than the bulk formula based estimates such as WHOI OA flux (Yu et al., 2004)

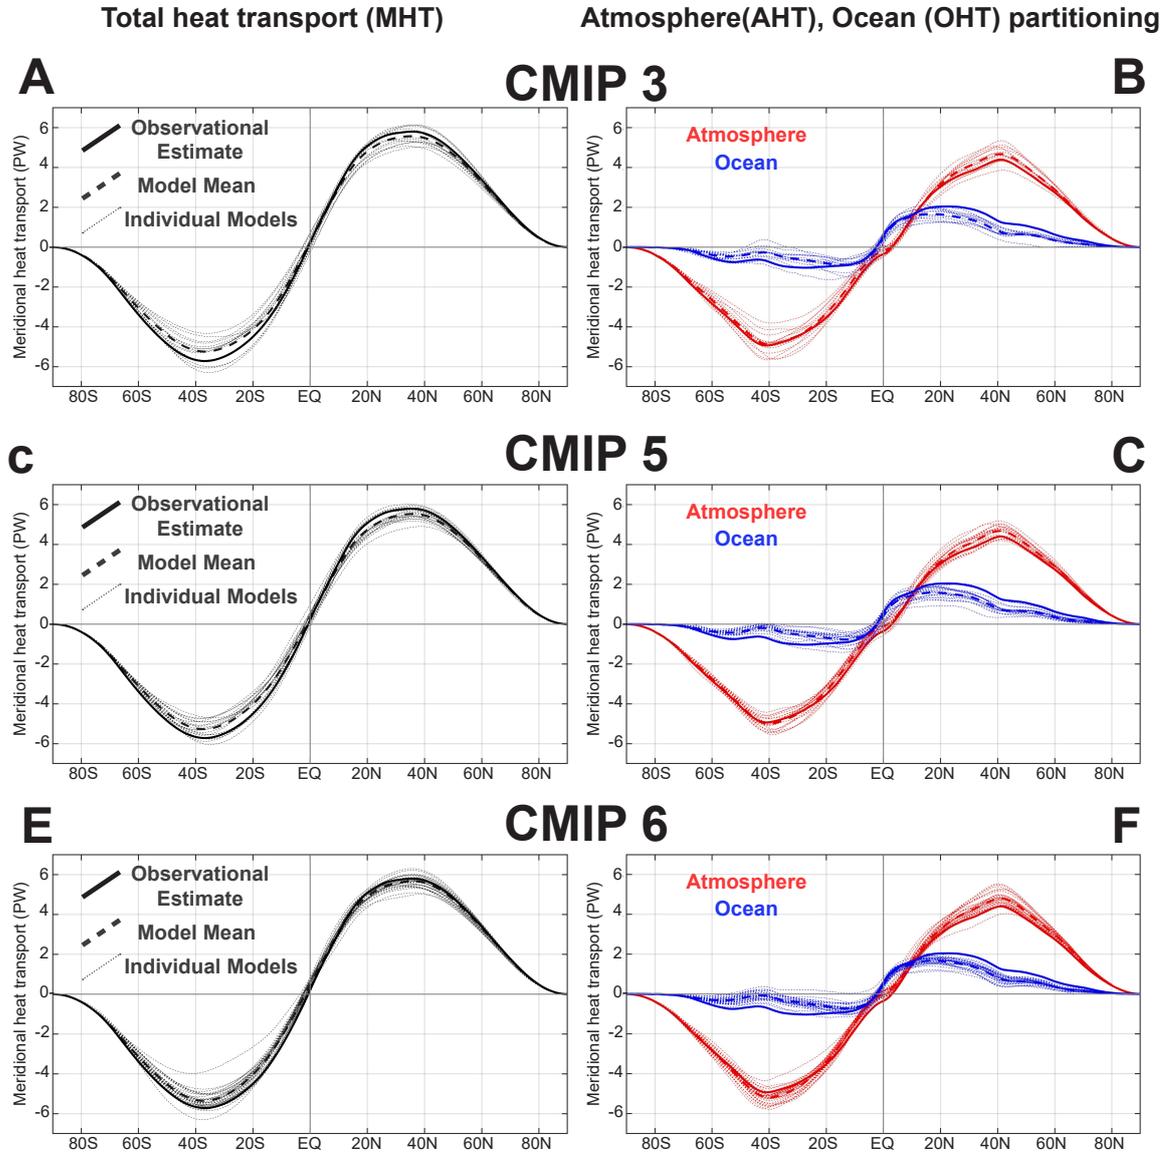

456 and SEAFLEX (Curry et al., 2004). We chose to use WHOI OA flux for the analysis in  
457 Section 4 because the bulk formula in this product are optimized to match buoy obser-  
458 vations – making it the most observationally constrained estimate of evaporation. Ad-  
459 ditionally, the global constraint of evaporation balancing precipitation is nearly satisfied  
460 from the combination of the WHOI OA FLUX evaporation over the ocean ( $62.8 \text{ W m}^{-2}$   
461 contribution to global mean) plus the ERA5 reanalysis evaporation over land ( $12.9 \text{ W}$   
462  $\text{m}^{-2}$  for a global total evaporation of  $75.7 \text{ W m}^{-2}$ ) nearly balancing the best observa-  
463 tional estimate of global mean precipitation ( $77.9 \text{ W m}^{-2}$ ) from the NOAA GPCP (Adler  
464 et al., 2018). The lack of closure of the observed global mean surface energy budget sug-  
465 ggests that observational surface radiation and/or turbulent energy fluxes are poorly con-  
466 strained and one hypothesized solution is that both global mean evaporation and pre-  
467 cipitation are substantially underestimated (Stephens et al., 2012). Our analysis circum-  
468 vents this debate by removing global mean quantities, showing that the equator-to-pole  
469 gradient of surface energy fluxes is consistent with that inferred from TOA radiation and  
470 AHT divergence. This suggests that the meridional structure of surface energy fluxes con-  
471 strained by TOA radiation and AHT could be used in conjunction with global mean im-  
472 balances to give an additional constraint for reconciling which terms in the observed sur-  
473 face energy budget are most uncertain and/or biased.

## 474 6 Open Research

475 All underlying observational data sets are publicly available. The CMIP data an-  
476 alyzed in this study can be found in the Earth System Grid392 Federation (ESGF) repos-  
477 itory at <https://esgf-node.llnl.gov/projects/esgf-llnl>. Observational calcula-  
478 tions of AHT from the vertical integral of 6 hourly reanalysis data (MERRA, ERA5, NCEP  
479 and JRA) are available at [https://atmos.uw.edu/~aaron/cmip\\_AHT\\_partition/](https://atmos.uw.edu/~aaron/cmip_AHT_partition/).

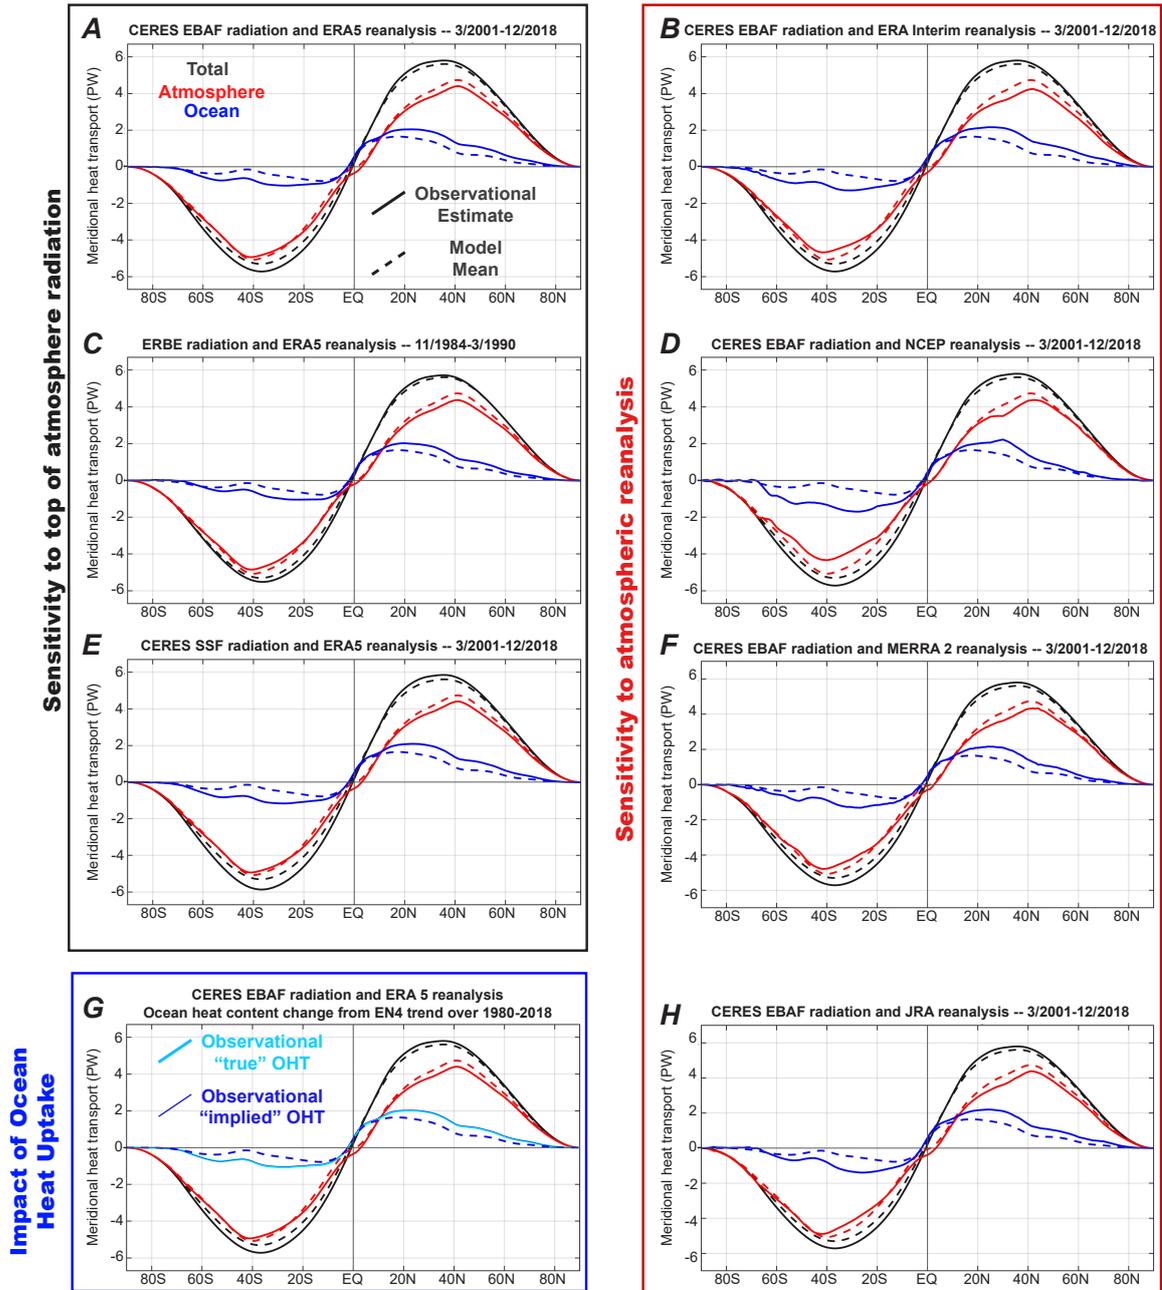

## 480 Acknowledgments

482 AGS-2019647. RF was supported by the NOAA Climate and Global Change Postdoc-  
483 toral Fellowship programs for the Advancement of Earth System Science (CPAESS) un-  
484 der award NA18NWS4620043B.

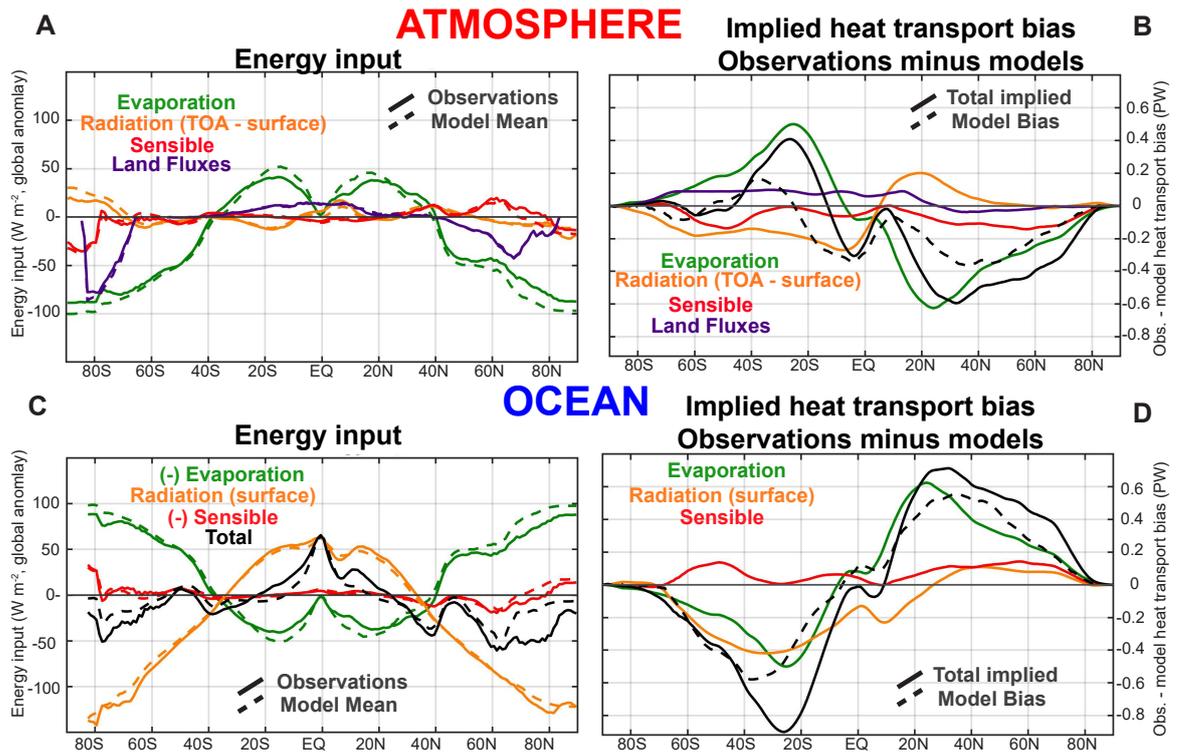

**Figure 1.** Observational and model (left panels) total meridional heat transport (MHT) and (right panels) its partitioning between the atmosphere (AHT, red) and ocean (OHT, blue). Results from the CMIP3, CMIP5, and CMIP6 models are shown in the top, middle and bottom panels respectively. The observational estimates are shown by the heavy solid line, individual coupled models are shown by the dotted lines and the model ensemble mean is shown by the heavy dashed line.

**Observational AHT/OHT partitioning in different radiation and reanalysis datasets**

**Figure 2.** Comparison of MHT, OHT and AHT in models and observations using eight different observational estimates of MHT (black solid), AHT (red), and OHT (blue). The left panels show the sensitivity of the transports to TOA radiation product used with CERES EBAF on the top panel, ERBE in the second panel, and the unadjusted CERES SSF on the bottom and with the ERA5 AHT estimate across all panels. The right panels show the observational transports calculated using CERES EBAF TOA radiation in all panels but using different atmospheric reanalysis products in each panel: (B) ERA Interim; (D) NCEP; (F) MERRA2 and; (H) JRA. Panel (G) shows the impact of observed spatial patterns in ocean heat storage on implied OHT using EN4 ocean heat content changes over 2000-2018. The model mean is the average over all models in CMIP3, CMIP5, and CMIP6 (CMIP-mean).

**Figure 3.** Model and observational estimates of the energy input into the atmosphere and ocean and the implied AHT and OHT biases resulting from each input. (A) Global anomaly energy input into the atmosphere in models (dashed) and observations (solid). See text for definition of terms. (B) Implied AHT bias (observations minus models) due to each energy input. The solid black line shows the sum of all terms. The dashed black line shows the bias in heat transport inferred from CERES and ERA5 data. (C) As in A but for the energy input to the ocean. (D) As in B but for the implied OHT bias.
