8   **Key Points:**

9   • LiDAR differencing (1999-2018) and SAR time series (2004-2020) show similar spatial
10   variations. LiDAR documents horizontal changes.
11   • Subsidence varies between zones separated by growth faults and correlates with
12   groundwater level changes and fluid injection.
13   • Creep along the Baton Rouge growth fault likely accommodates spatial variations in
14   subsurface fluid levels.

15

16   **Abstract**

17   The Coast of Louisiana is affected by accelerating sea level rise compounded by land
18   subsidence, leading to land loss. Vertical crustal motions in the region are caused by natural and
19   anthropogenic processes that vary temporally and spatially across the Gulf of Mexico. We
20   investigate the role of growth faulting contributions to subsidence in a case study of Baton
21   Rouge, where two E-W striking, down-to-the-south normal faults, the Denham Springs and
22   Baton Rouge faults, cut compacted Pleistocene strata, and where sediment compaction should be
23   minimal. We used InSAR time series and LiDAR differencing data spanning 1999-2020 to
24   quantify modern vertical and horizontal displacements. After calibration with GNSS data, both
25   methods reveal similar spatial patterns in ground motion, with the faults delimiting areas with
26   different absolute rates. On average the area north of the Baton Rouge fault is subsiding faster
27   than the south, opposite to the long-term sense of fault slip. LiDAR mean vertical rates range
28   between -5 to -11 mm/y and -2.4 to -7 mm/y. InSAR time-series mean rates in the LOS direction
29   range between -10.9 to -13.6 mm/y and -8 to -10.6 mm/y, respectively, for the north and south
30   areas. Subsidence in the northern area likely is controlled by groundwater level changes caused
31   by pumping as indicated by groundwater extraction models. The southern area average is likely
32   influenced by the injection of fluids. Our results suggest volumetric changes caused by fluid
33   extraction and injection in regions separated by growth faults that are creeping to accommodate
34   the spatial variations in subsidence.

35   **Plain Language Summary**
36   Coastal Louisiana is affected by the combination of sea level rise and ground surface sinking, or
37   subsidence. The contribution of subsidence due to natural and human activities varies in time and
38   space. We used airborne LiDAR and SAR satellite data to estimate rates and spatial variations of
39   vertical and horizontal surface motions between 1999 and 2020 in the metropolitan area of Baton
40   Rouge where two faults with surface topography cross the region in a pattern like tilted dominos.
41   We found that the entire area is experiencing subsidence, but that the subsidence rate is faster in
42   the northern fault block than in the southern block of the study area, this pattern is opposite to the
43   long-term fault motion. The spatial pattern of the results from LiDAR and SAR data are similar
44   and relate to groundwater pumping in areas of fast subsidence and wastewater injection zones in
45   areas of slow subsidence. Our results should be considered for future urban planning and water
46   management.
47

48   **Main Abbreviations**
49   Baton Rouge Fault (BRF); Denham Springs Fault (DSF); Digital elevation model (DEM); Gulf
50   of Mexico (GOM); Interferometric Synthetic Aperture Radar (InSAR); Iterative Closest point
51   (ICP); Light Detection and Ranging (LiDAR); Line of Sight (LOS); Margin of Error (MOE);
52   Persistent Scatter Interferometry (PSI); Relative sea-level (RSL); Root Mean Square Error
53   (RMSE); Sea Level (SL).
54

55   **1 Introduction**

56   Sea level (SL) rise caused by the combined effects of ice sheet melting and water column

57   expansion owing to increases in ocean temperature will affect at least 190 million people

58   worldwide living mainly in coastal areas (Milliman and Haq, 1996; Kulp and Strauss, 2019;

59   Frederikse et al., 2020). At regional scales, as in the Gulf of Mexico (GOM), thermal expansion

60   contributes greatly to SL changes (Frederikse et al., 2020). During the 20th century, global SL

61   increased between 12-15 cm (Milliman and Haq, 1996), and it is expected to rise 65 ±12 cm by

62   2100 (Church et al., 2013; Nerem et al., 2018). The rate of SL rise in the GOM region is

63   accelerating owing to a combination of oceanographic effects (Dangendorf et al., 2023).

64   Relative sea-level (RSL) is the sum of sea-level rise and vertical crustal motions caused

65   by natural and anthropogenic processes such as fluid extraction, compaction of recent sediments,

66   isostatic adjustments, salt movement, and growth faulting (NASEM, 2018) (Fig. 1). Previous

67   estimates of RSL rate along the Louisiana coast range between 1.38 – 13.2 mm/y; variations

68   between studies depend on methods and local factors (e.g., Penland and Ramsey, 1990;

69   Pendleton et al., 2010; Karegar et al., 2015; Jankowski et al., 2017). Quantifying the different

70   processes using only one method is not an easy task (e.g., Karegar et al., 2020), and all the

71   measurements from different methods should be in the same reference frame (e.g., Shirzaei et al.,

72   2021). Considerable work has been done to quantify rates of sediment compaction in southern

73   Louisiana using Rod Surface Elevation Table horizon markers (e.g., Jankowski et al., 2017;

74   Nienhuis et al., 2017). Quantification of Glacial Isostatic Adjustment (GIA) and anthropogenic

75   contributions lack adequate spatial distribution of GNSS receivers anchored in compacted

76   sedimentary strata across the region (e.g., Dokka 2006; Pendleton et al., 2010; Keogh and

77   Tornqvist, 2019; Karegar et al., 2020). Interferometric Synthetic Aperture Radar (InSAR) offers

78   excellent spatial resolution of vertical crustal movements, and earlier studies in the GOM have

79   detected local and regional variations using individual interferograms and time series (e.g., Jones

80   et al., 2016; Fiaschi and Wdowinski, 2020). Another method consists of using Light Detection

81   and Ranging (LiDAR) data from two different surveys to perform differential LiDAR (e.g.,

82   Nissen et al., 2012; Scott et al., 2018; Wheaton et al., 2010). Recently, Zhong et al., (2022) used

83   these two tools in coastal Texas and concluded that the high spatial resolution of LiDAR can

84   improve the results from InSAR time series. InSAR and LiDAR have a good spatial resolution,

85   but the temporal resolution is lower compared to other tools such as GNSS. Integrating all three

86   tools in one area is needed to unravel the causes and spatial variability of vertical crustal

87   movements is critical to mitigation and adaptation programs along the GOM.

88
89 **Figure 1: A)** Schematic model of the extensional-contractional complex in southern Louisiana. Faults included in
90 the figure: Baton Rouge Fault (BRF), Denham Springs Fault (DSF), Golden Meadow Fault Zone (GMFZ), Michoud
91 Fault (MF). Study area enclosed in red rectangle. Modified from Shen et al. (2017). **B)** Topographic profile of the
92 study area. Modified from Gasparini et al., (2015). **C)** Hydrogeological setting under the study area enclosed in (A).
93 Aquifer boundaries are an approximation for the lithologic, hydrogeologic, and aquifer system contacts. The top one
94 is the 400-ft sand and the bottom one is the 2800-ft (122 m and 853 m respectively) sand, after White (2017).
95 Subsidence and uplift rates from: Kuchar et al. (2018)[1], Dokka et al. (2006)[2], Dokka, (2006)[3], Chan et al. (2007)[4],
96 Shen et al. (2017)[5], Keogh and Törnqvist (2019)[6], Love et al. (2016)[7], Karegar et al. (2020)[8], Karegar et al. (2017)[9],
97 Penland and Ramsey (1990)[10], Jankowski et al. (2017)[11], Jones et al. (2016)[12], Penland et al. (2001)[13], Hopkins et al.
98 (2021)[14].

99   The Baton Rouge region east of the Mississippi River in southern Louisiana is crossed by

100 several E-W striking growth faults that have topographic relief of ~ 5 m, with Quaternary slip

101 rates of < 1 mm/y (Shen et al., 2017)(Figs. 1, 2, 3). Hopkins et al. (2021) measured deformation

4

102   of man-made structures of known age in the Baton Rouge-Lake Pontchartrain region to estimate

103   fault slip rates of ~3 mm/y. These rates are 10 times faster than time-averaged rates from Shen et

104   at. (2017) (Fig. 1). The faults cut compacted Pleistocene strata reducing the number of variables

105   contributing to ground subsidence. The study of Hopkins et al. (2021) indicates that fault slip

106   rates are within the range of detection of both LiDAR and InSAR.

107   Here we use LiDAR and SAR data spanning 1999-2020 to answer the following

108   questions for the Denham Springs Fault (DSF) and the Baton Rouge Faults (BRF) (Figs. 1, 3): 1)

109   Are subsidence rates caused by fault slip significant and measurable using one or both LiDAR

110   and SAR? 2) What areas are affected by fault-controlled subsidence in the Baton Rouge area? 3)

111   Do patterns of vertical crustal movements correlate with fluid extraction and/or urban

112   development? Answering these questions will enable us to verify or refute the following

113   hypotheses: Differencing LiDAR surveys of different periods can detect small vertical motion

114   signal with enough resolution to produce similar results to InSAR; and the BRF and DSF faults

115   are slipping locally due to anthropogenic activities or by natural causes, or a mix of both. *We*

116   *chose East Baton Rouge as a test study area because there are two growth faults displacing*

117   *Pleistocene sediments where Holocene sediment compaction is small, enabling us to isolate the*

118   *signals of fault creep and anthropogenic change (Figs. 1, 2).* We use information from two

119   continuous GNSS stations processed by the Nevada Geodetic Laboratory (Blewitt et al., 2018) as

120   control points in LiDAR and InSAR data sets. We also compare the results with well data from

121   the Louisiana Department of Natural Resources (SONRIS, n.d.) to investigate whether there is a

122   spatial correlation between fault slip and injection and extraction well volumes and rates over the
123   last two decades.

124
125 **Figure 2:** Baton Rouge study area with respect to the Gulf of Mexico margin in Louisiana showing GNSS sites,
126 water and oil/gas extraction wells and injection wells. The Denham Springs (DSF) and Baton Rouge (BRF) are
127 growth faults with Holocene slip (Shen et al., 2017). The Northern block lies between the DSF and BRF; the
128 Southern block is the hanging wall of the BRF. Inset shows the location of the study area with respect to the
129 Mississippi delta, surrounding states, and main fault systems in Louisiana. Michoud fault (MF), Golden Meadow
130 fault zone (GMFZ) and the faults used by Hopkins et al. (2021) (H) are shown. MRA is Mississippi River Alluvial
131 Aquifer. Fault scarps from Culpepper et al. (2019b). Well data and aquifers from the Louisiana Department of
132 Natural Resources (SONRIS), (n.d.). GNSS stations from the National Geodetic Survey (n.d.). Gray vertical lines
133 and numbers are profiles for Figure S1. Base map imagery from QuickMapServices - QGIS (Map data ©2015
134 Google).

135 **1.1 Background**
136   The GOM is a passive margin that formed between 200-158 Ma during the breakup of

137 Pangea, resulting in pervasive, general E-W-striking normal fault systems bounding 3-10 km-

138 deep sedimentary basins (e.g., Sawyer et al., 1991; Pindell and Kennan, 2009; Eddy et al., 2014).

139 Mesozoic growth faults in the Mississippi delta are listric faults that detach on salt horizons

140 (Durham and Peeples, 1956; Culpepper et al., 2019). These faults accommodated extension until

141 ~40 Ma, but much slower movement associated with compaction and salt migration has

142 continued to present day (Shen et al., 2017). Despite the ~5 m fault scarps (Fig. 3) and evidence

143 for ongoing movement, there are only three instrumentally recorded earthquakes of M2.4-3.8

144 along the coastal fault systems of Louisiana (Stevenson and Agnew, 1988; Walter et al., 2016),

145 suggesting that slip occurs primarily by creep.

146   The GOM is characterized by its low elevation coasts, broad continental shelf, steep

147   continental slope, and a basin as deep as 4400 meters (e.g., Turner and Rabalais, 2018). The

148   Mississippi River flows into the GOM, through the Mississippi delta. The delta began to develop

149   at ~100 Ma with the formation of the Mississippi embayment, which concentrated sediment

150   input to the gulf. During the last 7000 years, the delta depocenter relocated at least six times in

151   response to climate and sea-level changes (Blum and Roberts, 2012). In the last 100 years, the

152   Mississippi delta has suffered drastic land loss (Gagliano et al., 1981). This could lead to a shift

153   of the depocenter of the Mississippi delta caused by sea-level rise, climate change, anthropogenic

154   activities, and the lack of sediment delivery caused by artificial dams (e.g., Blum and Roberts,

155   2012). Glacial Isostatic Adjustment (GIA) and Sediment Isostatic Adjustment (SIA) contribute to

156   long-term subsidence (e.g., Kuchar et al., 2018). GIA was modeled using RSL data from tide

157   gauges and vertical and horizontal velocities from GNSS between 2006-2015 along the GOM by

158   Love et al. (2016). During this century GIA in southeast Louisiana will contribute approximately

159   30 mm to RSL rise with a rate of 0.32 mm/y (Love et al., 2016). On the other hand, SIA registers

160   a rate of less than 0.5 mm/y on areas with thicker Holocene sediments (Wolstencroft et al., 2014;

161   Kuchar et al., 2018).

162   Holocene sediment thickness increases following the shape of the Mississippi river,

163   reaching a thickness of 100 meters at the shoreline (Penland and Ramsey, 1990). Compaction

164   and compression of Holocene sediments are the primary factors causing subsidence on the

165   Mississippi delta in areas close to the shoreline (e.g., Penland and Ramsey, 1990; Karegar et al.,

166   2015; Karegar et al., 2020). Shallow subsidence in the uppermost 5 meters in the Mississippi

167   delta accounts for more than 60% of the total subsidence in the coastal area with rates varying

168   between 6.4±5.4 and 9±1 mm/y (Keogh and Törnqvist, 2019; Jankowski et al., 2017; Nienhuis et

169   al., 2017).

170   Despite the importance to infrastructure, there are just a few studies that have quantified

171   fault slip rates and their relationship with subsidence at different time scales in the area, with

172   rates ranging between 0.02 – 16.9 mm/y (Gagliano et al., 2003a, 2003b; Dokka et al., 2006; Shen

173   et al., 2017; Culpepper et al., 2019a; Hopkins et al., 2021). Fault slip and creep are difficult to

174   quantify because they can be episodic and slow, and the signal can be masked by faster processes

175   such as sedimentation (Gagliano et al., 2003b). Salt movement may reactivate some fault

176   segments (Gagliano et al., 2003a). Local subsidence has been related to the presence of fault

177   traces and fluid extraction sites (e.g., Kuecher et al, 2001; Morton et al, 2002; Dokka, 2011).

178   Dokka (2006) and Dokka et al., (2006) interpreted episodes of subsidence along the Michoud

179   fault (MF) between 1955 to 2005 as evidence of episodic fault slip, although they could also be

180   caused by groundwater extraction (Jones et al., 2016). Fault motion and subsidence near the

181   Golden Meadow fault zone (GMFZ) have been related to hydrocarbon extraction (e.g., Morton et

182   al., 2002; Chan and Zoback, 2007).

183   There is visual evidence of building and road displacements along the BRF and other

184   coastal faults with measured rate estimates of ~3 mm/y (McCulloh, 2001; Hopkins et al., 2021).

185   The BRF and DSF reactivated during the Pleistocene due to depositional loading (McCulloh and

186   Heinrich, 2013). Shen et al. (2017) calculated mean fault throw rates in the eastern portion of the

187   BRF using optically stimulated luminescence dating. Their results indicate that the faults have an

188   average slip of 0.22 mm/y for the past 4,000 years and between 0.02-0.07 mm/y for the last

189   130,000 years for areas lying on Pleistocene sites. The relief caused by Pleistocene-Recent slip

190   along the BRF is clear in DEMs produced from LiDAR data (Fig. 3). Faults in this system merge

191   at a depth of ~6 kilometers into a detachment that sits on an overpressured layer of salt and shale

192   that dips with an angle between 45° to 65° (Gagliano et al., 2003a; Shen et al., 2017) (e.g., Figs.

193   1).

194   Local subsidence has been related to the presence of fault traces and fluid extraction sites

195   (e.g., Kuecher et al, 2001; Morton et al, 2002; Dokka, 2011). Wells in Baton Rouge have

196   multiple purposes like water, gas and oil withdrawal, water injection and monitoring, with depths

197   ranging between 4-6000 meters. The change of pore fluid pressure underground caused by fluid

198   extraction/injection changes the volume at depth, which could influence fault activation (e.g.,

199   Kuecher et al., 2001). Multiple studies have related extraction of fluids with local subsidence at

200   different locations (e.g., Jones et al., 2016; Puskas et al., 2017; Li et al., 2020), and uplift with

201   injection of fluids (Teatini et al., 2011; Shirzaei et al., 2016).
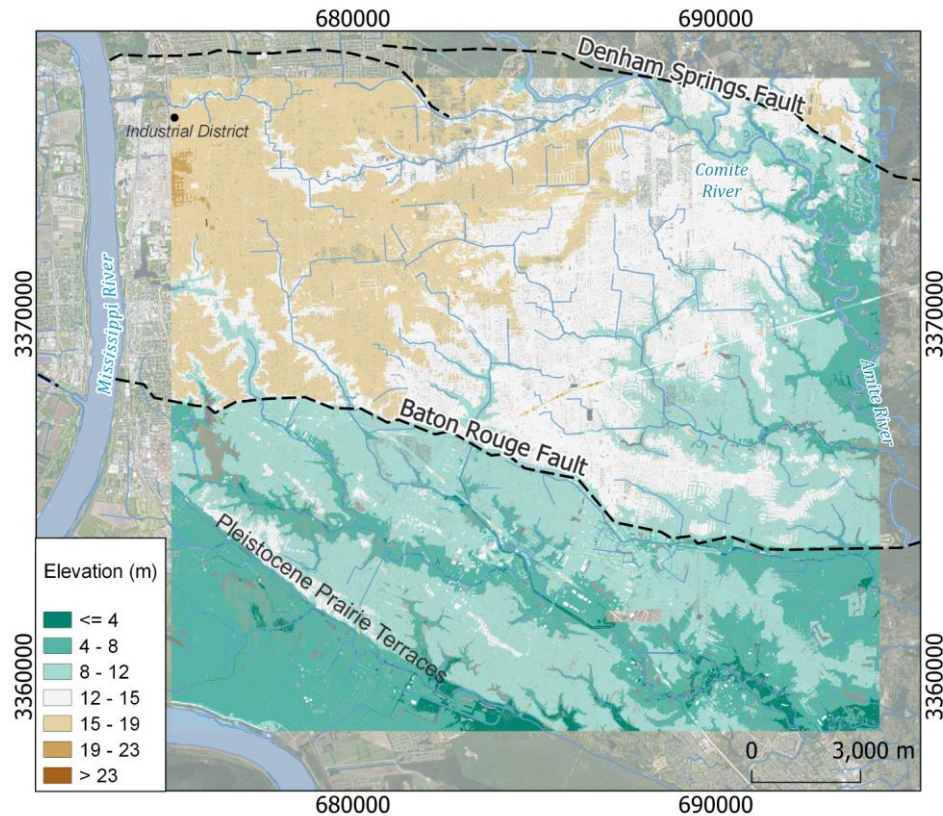

202
203 **Figure 3:** Digital Elevation Model from the study area showing the topographic relief across the Denham Springs
204 and East Baton Rouge faults (dashed lines). The geological contact labeled as Pleistocene Prairie Terraces marks the
205 edge of the natural levee in the area. We created this DEM using LiDAR point cloud from the 2018 survey. Base
206 map imagery from QuickMapServices - QGIS (Map data ©2015 Google).

207   The aquifer system in Baton Rouge is part of the Southern Hills aquifer and the

208 Mississippi River Alluvial aquifer (Tomaszewski et al., 2002) (Fig. 2). The former is composed

209 of interbedded layers of compressed clay/silt and layers of porous sands (Fig. 1). The sands south

210 of the BRF are more continuous than those north of the fault (Vahdat-Aboueshagh and Tsai,

211 2021). These sands form ten independent aquifers named after their depth under the Baton

212 Rouge industrial district, with depths between 122 to 823m (400 ft to 2700-ft) (Tomaszewski et

213 al., 2002). Large volumes of groundwater removal have affected reservoirs in the Baton Rouge

214 area forming cones of depression at local and regional scales (White, 2017; Chen et al., 2023),

215 and saline water from southern areas has intruded into some of these sands (Nasreen, 2003;

216 Elshall et al., 2013). Similarly, other areas in Louisiana have shown saline intrusion in areas of

217 fault motion (e.g., Kuecher et al., 2001). Deep aquifers have larger withdrawal volumes, and,

218 therefore, have been more affected during the last decades (Tomaszewski et al., 2002; Nasreen,

219 2003). The Mississippi River Alluvial aquifer has not had a significant groundwater level

220   decrease, and saline water has not infiltrated the eastern portion of the aquifer where the study

221   area is located (Tomaszewski et al., 2002; Nasreen, 2003; Chen et al., 2023).

222   The BRF plays an important role in the dynamics of the aquifers in Baton Rouge; it is a

223   barrier for saline water coming from the southern area, but it may serve as a conduit and can

224   allow lateral intrusions due to pumping of groundwater at the north of the fault (Nasreen, 2003;

225   Elshall et al., 2013; Anderson et al., 2013; Chen et al., 2023). The DSF is permeable and allows

226   freshwater to flow down to the south, where pressure gradients cause southward flow and

227   recharge to the aquifers in the area between the two faults (Elshall et al., 2013).

228   **2 Data**

229   **2.1 SAR data**

230   SAR datasets were acquired by the EnviSAT and Sentinel-1 satellites. Both acquire data

231   on the C-band (5.405 cm) and produce Single-Look Complex images. We used vertical transmit

232   and receive polarization (VV). The EnviSAT dataset was collected between 2004 and 2010 in

233   the relative orbit 83 and it is composed of 18 scenes (ESA, 2021a) in descending mode. The

234   Sentinel-1 dataset was collected in Interferometric Wide mode between 2017 and 2020 and

235   consists of 33 scenes all acquired in the relative orbit 165 (ESA, 2021b) in ascending mode. Each

236   of these datasets forms a different time series that was analyzed separately. The list and dates of

237   images is in Table S1.

238   **2.2 LiDAR data**

239   LiDAR point clouds come from two surveys that cover the portion of the BRF and DSF,

240   East Baton Rouge parish. The first dataset was collected in March of 1999, has a point space of 4

241   m (0.0625 points/m^2), a pulse rate of 15 kHz and a vertical accuracy measured as the Root Mean

242   Square Error (RMSE) of 15 cm (USACE, 2001). The newest was collected between March and

243   April of 2018, has a point space of 0.33 m (9.2 points/m^2), a pulse rate of 450 kHz and a vertical

244   accuracy of RMSE=3.6 cm (USGS, 2019). For more details see Table S2.

245   **2.3 Well data**

246   Data about injection and extraction of fluids from the wells comes from the Louisiana

247   Department of Natural Resources website. The wells included here are those that were active

248   between 1999 and 2020 or for a shorter time in that period and were in the database by August

249   2021. For wells extracting water, we only used active wells whose main function was water

250   pumping. In the case of wells producing oil and gas, we only considered those with gas

251   production of at least 200,000 MCF or produced more than 20,000 m^3 of oil during the study

252   period (Fig. S4). Not all the wells have complete information about volume of production or

253   injection, but if they appeared as active, we included those for location information in our maps.

254   Table 1 summarizes the number of wells found and used. However, wells that were operating

255   before can, in some cases, caused delayed pore pressure changes and deform the surface

256   (Shirzaei et al., 2016).

257

258   **Table 1**: Number of wells in the study area per fluid. This table excludes 1908 wells that are used to monitor water
259   level and quality.

	Water	Oil – gas	Injection
Total wells in area	821	368	24
Current active wells (By august/2021)	470	6	2
Active wells between 1999 -2021	592	47	13
Wells with volume extraction/ injection information		23	9

260

261   **2.4 GNSS time series**

262   There are two continuous GNSS stations in the study area (Fig. 2). Both stations are

263   mounted on buildings and there is no public information about the foundation depth for any of

264   the stations. The 1LSU station worked between 2004-2022 and it is mounted on the Patrick F.

265   Taylor Hall building, constructed on the Mississippi River Alluvial Aquifer (Fig. 2) and the

266   Pleistocene Terraces (Fig. 3). The local geology makes the 1LSU site sensitive to hydrological

267   changes of the Mississippi River as compared to the SJB1 station. The SJB1 station has acquired

268   data between 2009-2023 and it is mounted on the LifeShare Blood Center constructed above the

269   Southern Hills aquifer which lies at deeper depths than the Mississippi River Alluvial Aquifer

270   and does not have direct contact with any water body (Fig. 2). North, east, and up velocities of

271   the GNSS stations are calculated by the Nevada Geodetic Laboratory (Blewitt et al., 2018).

272   Vertical time series for both stations are in Fig. S3.

11

273 **3 Methods**

274 **3.1 Persistent Scatter Interferometry - PSI (time series InSAR)**

275 PSI is a differential InSAR technique that allows one to use the phase information from

276 multiple SAR images acquired at different times to estimate phase changes between several

277 interferograms. Phase change information is used to calculate the velocity of displacement and

278 the displacement time-series during the study period (Hooper et al., 2004; Crosetto et al., 2016).

279 PSI uses pixels with low phase noise, called Persistent Scatterers (PS), across lengthy time

280 intervals in multi-temporal data. It is particularly useful in urban areas that have a high density of

281 persistent, or permanent, scatterers (Ferretti et al. 2001; Crosetto et al., 2016). Displacement is

282 calculated on the Line of Sight (LOS), projecting 3D displacements into 1D displacements in the

283 LOS direction (Crosetto et al., 2016). One of the advantages of this technique is its ability to

284 detect signals of ground displacement at millimetric scales with an accuracy of millimeters

285 depending on the number of images in the time series, the density of PS, temporal baseline

286 dispersion, and terrain conditions (Ferretti et al., 2001; 2004; 2007).

287 A description of this technique is found in the official manuals (L3Harris, 2014; 2021),

288 Ferretti et al., 2001, and in the Supplemental material (T1). We used SARscape software (version

289 5.6; 2021) to calculate vertical displacement velocity for both datasets. The topographic phase

290 was removed using the Shuttle Radar Topography Mission DEM. Orbital errors can be ~0.5

291 mm/y/100 km for EnviSAT and ~0.2mm/y/100 km for Sentinel-1 in the LOS direction (Fattahi

292 and Amelung, 2014), but effectively cancel for InSAR time series with several images as the

293 ones presented here. Ionospheric errors are negligible because we are using data captured on the

294 C-band and the study area is at midlatitude where ionospheric corrections are not recommended

295 (Liang et al., 2019). Tropospheric phases are estimated from the residuals from the linear model

296 calculated by SARscape (Ferretti et al., 2001; Supplemental material - T1). To provide a

297 numerical approximation of the tropospheric variation over the study area during the study

298 period we present an empirical analysis using GACOS data (Yu, et al. 2017; Supplemental

299 material – T2). For the EnviSAT time series (2004-2010) the average range of the tropospheric

300 delay is 28.75 mm and for Sentinel-1 time series (2017-2020) it is 35.95 mm.

301 We multilooked the data to reduce decorrelation noise and build the spatial coherence

302 map (Goldstein et al., 1988; Fig. S5). For the EnviSAT dataset we used four azimuth-looks and

303 one range-look; for the Sentinel-1 dataset we used five azimuth-looks and one range-look. The

304   entire area is divided into sub-areas, each is 25 km^2 and every subarea is independently

305   processed. By default, just one reference point is selected for each subarea. Reference points

306   were selected using an Amplitude Dispersion Index >60%. A 30% overlap of subareas is used in

307   the mosaicking process to merge all the sub-area results. The merging process is carried out

308   considering a Super Reference Point (Fig. 4 and 5) which is characterized by the highest

309   Amplitude Dispersion Index among the others. Coherence used for merging all sub-areas is 0.77.

310   **3.2 LiDAR pre co-registration**

311   Co-registration of the LiDAR point clouds is the process of aligning datasets acquired at

312   different times over the same area. It is important to know the magnitude and the direction of the

313   horizontal misalignment to correct the geographical location of the point clouds to improve

314   vertical differencing between corresponding points. This process reduces systematic errors

315   (Anderson, 2019). Misalignments between the point clouds can be caused by 1) distortion of the

316   point clouds from measurement errors related to flight discrepancies; 2) real changes in the

317   landscape (subsidence, uplift, translation, vegetation growth, mass movement); and 3) local

318   topographic relief on flat surfaces where there is less random LiDAR scattering (Scott et al.,

319   2018).

320   We conducted point cloud co-registration using ICP (Section 3.3) in two ways: using

321   only LiDAR ground points and using LiDAR points from structures that should be stable over

322   time and are anchored to some foundation depth (e.g., Fig. S2). For the first approach, ground

323   points were taken using the original classification of both point clouds done by the distributors.

324   For the second approach, a feature-based technique allows us to take information from structures

325   that are expected to be stable and use them as control points (Brook and Ben-Dor, 2011). Using

326   Point Data Abstraction Library (2018) filters (PDAL), we created a new point cloud for each

327   dataset whose points only belong to structures that satisfy specific criteria. First, the point must

328   be on a plane. To evaluate this criterion, we used the filter "estimaterank", which categorizes

329   each LiDAR point in a line, plane, or a 3D structure. Secondly, the points must be in an elevation

330   range assigned depending on if they are in the hanging wall or footwall of the BRF. The range

331   for the hanging wall is 7 m to 35 m and for the footwall is 12 m to 35 m. These values were

332   chosen from observation of the LiDAR data, using the maximum value from tall buildings and

333   the lowest from roads and parking lots. DEMs show that there are at least ~5 m of relief along

334   the BRF (Fig. 3); therefore, features on the hanging wall are expected to be at a lower elevation.

335   We allowed for North and East movements of the 2018 (newest) point clound to co-

336   register the 1999- and 2018-point clouds. The translation amount was estimated by ICP. We

337   calculated the average motion in the east and north components for areas of 2.25 km^2. This

338   process ensures that vertical DEM differencing is more accurate. We did this process with

339   ground LiDAR points and LiDAR points from stable structures.

340   **3.3 Iterative Closest point – ICP**

341   This algorithm allows one to perform 3D LiDAR differencing by calculating rotations

342   and translations of a surface (Scott et al., 2018; Nissen et. al., 2012). The ICP algorithm aligns

343   the point clouds using user-defined core points in the two datasets. Each core point is defined by

344   a grid of 50 m and centered in a square or window of 50x50 m in the 1999-point cloud and

345   51x51 m in the 2018-point cloud. We chose these values for computational optimization. The

346   horizontal coordinates of each core are the central point in each window. ICP assumes that each

347   window behaves as a rigid body (Nissen et. al., 2012).

348   This algorithm iterates as follows for each window: 1) Find the closest point in the old

349   point cloud for each point in the new point cloud, 2) Calculate translation and rotation of each

350   point in the old point cloud, 3) Iterate until a minimum distance is reached or until a certain

351   number of iterations are completed (Scott et al., 2018; Nissen et. al., 2012). We iterated until the

352   translation was less than 10^{-4} meters or when 10 iterations were completed. ICP applies a linear

353   transformation to the old data to have the best alignment possible. It finds the rigid body

354   transformation matrix, with α, β and γ representing the rotations on the x, y, and z axes, and $\boldsymbol{t_x}$,

355     $\boldsymbol{t_y}$, $\boldsymbol{t_z}$ representing the translations in the same three axes in equation 1 (Scott et al., 2018).

356
$$PC_{new} \approx PC_{old\ transformed} = \begin{pmatrix} 1 & -\gamma & \beta & t_x \\ \gamma & 1 & -\alpha & t_y \\ -\beta & \alpha & 1 & t_z \\ 0 & 0 & 0 & 1 \end{pmatrix} PC_{old} \qquad (Eq.\,1)$$

357   Where PC_{new} is the newest LiDAR point cloud, in this case the one from 2018, PC_{old} is the

358   original and oldest LiDAR point cloud, here corresponding to the one from 1999, and

359     $PC_{old\ transformed}$ is the transformed old LiDAR point cloud. We run the ICP algorithm with LiDAR

360   ground points and with LiDAR points from stable surfaces chosen in the co-registration section.

361   In both cases, ~122,400 core points and windows were created. The windows do not have the

362   same number of LiDAR points. The results of this ICP implementation provide the amount of

14

363   translation that must be applied to each window in the newest point cloud to align the dataset

364   with the oldest point cloud. The translations of each window are represented on each core point.

365   These results were filtered to have only displacements between 0 to 1 m to eliminate

366   outliers (e.g., new constructions), and not natural displacements. Then, results were averaged to

367   have a representative point per 2.25 km^2. The error for this process is given initially by the Point-

368   to-Plane error metric (Scott et al., 2018; Nissen et. al., 2012), and the final averaged results were

369   evaluated using a 95% margin of error and the residual systematic error described on section 3.5.

370   We use the 3D_Differencing MATLAB code created by Scott et al. (2020) to apply ICP to

371   LiDAR data, which uses the LIBICP (LIBrary for Iterative Closest Point fitting) software created

372   by Geiger et al. (2012) to solve the rigid body transformation. The horizontal translations

373   calculated by ICP are used to co-register the datasets (Section 3.2), but these displacements can

374   include real motion. We discuss the real part of this motion in the results and discussion sections.

375   **3.4 Vertical DEM differencing**

376   Vertical differencing between the two data sets is achieved using Geomorphic Change

377   Detection (GCD) software. It allows one to detect topographic and volumetric changes using

378   digital elevation models (DEM) (Wheaton et al., 2010). With GCD we created a DEM of

379   Differences doing pixel by pixel differentiation. The vertical accuracy of these is given by

380   standard error propagation and depends on the accuracy of the original point clouds (Wheaton,

381   2018). We created the DEMs using PDAL filters to include only co-registered ground LiDAR

382   points. We used Inverse Distance Weighting with PDAL tools to interpolate the data (Shepard,

383   1968). We used a pixel size of 5 m, and a radius of 5 m for the 1999-point cloud and 3 m for the

384   2018-point cloud. The radius is different to ensure that the DEMs from 1999 have enough points

385   to interpolate. We used a power parameter equal to 2 because it has been shown to produce good

386   empirical results and it is computationally efficient (Shepard, 1968). The error of each DEM with

387   respect to the original LiDAR data was estimated using the root mean square error metric. Figure

388   S10 shows the workflow followed to process the LiDAR data.

389   **3.5. Error estimation**

390   Systematic errors can impact the estimated changes from LiDAR. As we co-registered

391   the data, it is expected that systematic errors caused by flight discrepancies are reduced but not

392   completely removed (e.g., Anderson, 2019). This error type can dominate the error budget in the

393   analysis of vertical ground changes (e.g., Anderson, 2019). We assume a residual systematic

394   error from the LiDAR results (Fig. 7A and 7B) of 44.8 mm (2.3 mm/y). This number is the

395   difference between the results of ground and stable surfaces on the fourth row from Figure 7A

396   and 7B where ab E-W stripe appears. The systematic problems are probably E-W flight line

397   errors.

398   We present uncorrelated random errors as the Margin of error (MOE) of the Mean. It is

399   calculated as $MOE_m = z \times \frac{\sigma}{\sqrt{n}}$. Where $z =$1.96 corresponds to a confidence level of 95% for the

400   average mean, σ is the sample standard deviation of the mean averaged points, and n the sample

401   size. We used this metric to quantify the random component of the error due to the different

402   areas for each sampling (2.25 km^2 and for each block of the fault ~175 km^2), but not for

403   individual points. The total uncertainties should include the RSE to better bound the results.

404   In the case of LiDAR, we are aware that each survey has an associated RMSE estimated by the

405   distributor (Section 2.2). The RMSE quantifies the discrepancy between the location of

406   checkpoints and the Triangulated Irregular Network generated from the point clouds by the

407   distributors (USACE, 2001; USGS, 2019). Then, in the worst case, each pixel on each DEM can

408   be wrong by 15 cm and 3.6 cm in the vertical component, if each pixel in each DEM only

409   contains one LiDAR point from each survey, and the vertical change in each pixel could have an

410   error of 15.43 cm. This extreme case is not a concern owing to our approach of comparing areas

411   from each survey and not individual pixels. For instance, each ICP - LiDAR window of 50 m

412   may have ~100 LiDAR points in each point cloud. Using the results of displacement for each

413   window (Section 3.3) we found the mean vertical displacement for 2.25 km^2 areas, then we

414   calculated the corresponding MOE with the number of windows (~1000) as the sample size. For

415   InSAR time series we present MOE using the total number of PS points for each block as the

416   sample size. Systematic errors for InSAR time series were corrected during the PSI processing

417   and their ranges are described (Section 3.1 and Supplemental material – T1).

418

419   **3.6. Tie of Results**

420   We used the 1LSU station as a tie point for all the results but EnviSAT and SJB1 as a

421   control point to compare the results after this connection. We selected 1LSU because has the

422   longest time series between the two stations. The results from the three geodetic tools (GNSS,

423   InSAR time series, and LiDAR differencing) are in different reference frames, so we

424   transformed the GNSS velocities (with plate fixed) from ITRF2014 to NAD83 using the online

425   application Horizontal Time-Dependent Positioning from NOAA (Pearson and Snay, 2013).

426   To tie the results, we calculated the difference between the displacement of 1LSU and the

427   results from LiDAR and InSAR time series in the location of the station. Then, that difference is

428   added/subtracted from each dataset to match the results with the results of the 1LSU station in

429   that location, such that all the results are referred to the same point (Mahatra et al., 2018). The

430   InSAR time series were tied to 1LSU by projecting to the LOS displacements of the station using

431   the incidence and heading angle for each dataset. For ICP, the tie with 1LSU was done in the

432   three components, and for LiDAR differencing it was done only in the vertical component. Due

433   to this process, the original results are moved by a constant, and this process does not change the

434   errors.

435   **4 Results**

436   **4.1 Velocities from InSAR time series – Envisat and Sentinel-1**

437   The results of the InSAR time series created with Sentinel-1 data do not show results for

438   the footwall of the DSF (Fig. 4) and the results from EnviSAT are very noisy to interpret (Fig.

439   5). The area covered by our study area at the north of the DSF is mostly covered by vegetation,

440   so there is high decorrelation and there are not enough persistent scatterers (Fig. 4B). We

441   therefore focus on the BRF.

442   For the case of discussion, we call the footwall block of the BRF the northern block and

443   the hanging wall of the BRF the southern block as indicated in Figure 2. After removing the

444   difference of motion with the GNSS station 1LSU from the results, the InSAR time series using

445   Sentinel-1 indicates that the northern block is moving away from the satellite at a larger rate than

446   the southern block (Fig. 4A). PSI detected 411,857 persistent scatterers. Areas labeled as

447   Agricultural, or Park/Water (Fig. 4B) do not have enough persistent scatterers. Therefore, we

448   cannot produce results over these areas with PSI. The mean velocity between 2017-2020 using

449   Sentinel-1 data for the complete northern block is -13.65±0.00471 mm/y while the southern

450   block has a mean velocity of -10.559±0.00895 mm/y. The SJB1 station differs from the InSAR

451   time series in ~2.33 mm/y (Fig. 4).

452   Figure 4C shows some examples of the time series in the area. Each time series is the

453   average displacement of the persistent scatterers that are in a specific location (details in Table

17

454   S3). The time series of P6 shows less displacement; it is located on the Baton Rouge Wastewater

455   Treatment plant which lies ~500 m from injection well 200837 and ~2000 m from the 136676

456   injection well. The time series for the building where the SJB1 station is anchored and the area

457   P5, which surrounds the injection well 189576, are the next series with less displacement. The

458   areas identified as P2, P3, and P4 have similar displacements and are the sites closest to the

459   BRF.

460

461   **Figure 4:** Rates produced with Sentinel-1 (2017-2020) compared to Land use. **(A)** Displacement rates in the LOS
462   direction calculated with the PSI method. These results are tied to the 1LSU GNSS station. Numeric labels in the
463   image indicate mean rates for the black dots. The cross is the initial reference point used to create the time series.

464 Rhombuses are the average velocities of the GNSS CORS stations in the LOS direction on the Sentinel-1 geometry
465 (ILSU -10.88 mm/y and SJB1 -8.404 mm/y). **(B)** We mapped land use using the basemap imagery from
466 QuickMapServices - QGIS (Map data ©2015 Google) at a scale of 1:10.000. **(C)** Time series examples located in
467 (A); green colors show samples in the northern block and purple colors show samples in the southern block. These
468 time series are the average of the displacements of the points that landed in the same construction, with details on
469 Table S3. Displacement in the LOS direction.

470   The velocity in the LOS direction for the study area using EnviSAT data is shown in

471 Figure 5A. This dataset does not cover the 1LSU station, and it is the only one that was tied to

472 the SJB1 station. The PSI process detected 172,791 persistent scatterers. These results are noisy

473 in some areas, although it is possible to see similar patterns with the results of Sentinel-1

474 analyses. Figure 5A shows that the entire area is subsiding but the northern block is moving

475 away from the satellite faster than the southern block. The northern block is moving with a

476 velocity of -10.869±0.0384 mm/y and the southern block at a rate of -8.030±0.0614 mm/y. The

477 noise also can be related to land-use changes during that period after Hurricane Katrina in 2005.

478 This will be further explained in the discussion section.

479   The example time series with EnviSAT shows that the P3 area was the most stable

480 among these examples, although it is close to the reference point of the time series in this dataset.

481 Sample P3 shows a large mismatch between the Sentinel-1 and EnviSAT results (Fig. 4C and

482 5B), but this area has homes constructed in 2017, before the area showed fewer coherent

483 persistent scatterers in EnviSAT as compared to Sentinel-1 data. We suspect that the change in

484 land use contributes to differences between datasets. The other areas show a similar behavior

485 (Fig. 5B). Details about each time series are in Table S3.

Figure 5: Rates produced with Envisat data (2004-2010) **(A)** Displacement rates in the LOS direction produced using the PSI method. These results are tied to the SBJ1 GNSS station. Numeric labels in the image indicate mean rates for the black dots. The cross is the reference point used to create the time series. Rhombuses are the average

490 velocities of the GNSS CORS stations in the LOS direction on the EnviSAT geometry (ILSU -9.81 mm/y and SJB1
491 -7.23 mm/y). **(B)** Time series examples located in (A); green colors show samples in the northern block and purple
492 colors show samples in the southern block. These time series are the average of the displacements of the points that
493 landed in the same construction, with0020details on Table S3**.** P2 and P6 do not have a time series because the
494 construction was not in place before 2010. Displacement in the LOS direction. Base map imagery from
495 QuickMapServices - QGIS (Map data ©2015 Google).
496

497 **4.2 LiDAR Horizontal displacement from ICP**

498 The results from ICP indicate that overall, the entire area moved towards the east

499 direction between 1999-2018 in the NAD83 reference frame (Fig. 6). Results of horizontal

500 displacement created with two different LiDAR classifications – ground LiDAR points and

501 stable surface LiDAR points (Fig. 6B) – have different spatial behaviors in some areas.

502 Horizontal displacements estimated using just ground LiDAR points (Fig. 6A) are more

503 homogenous showing that the whole area moved to the east with small displacements in the

504 north component (Table 2).

505 The horizontal displacement calculated using LiDAR points on stable surfaces shows

506 more heterogenous behavior (Fig. 6B). In the north area of the northern block most areas moved

507 to the east direction, but in the southeast of the same block near the BRF, the direction is mostly

508 north-east (Table 2). These results also show that the largest errors occur in the areas closer to

509 the eastern section of the BRF. A caveat of only using LiDAR points on stable surfaces is that

510 this set of points is less dense than the set of ground points, and affected mostly by the oldest

511 LiDAR survey, which may explain why the errors are smaller in the case of only ground LiDAR

512 points.

513 Our results agree in the direction of motion with the motion of the SJB1 station (Fig. 6,

514 Table 2). The magnitude of the motion using the rates from the GNSS SJB1 station between

515 1999-2018 is 42.18 mm to the north and 260.11 mm to the east. Comparison to the results with

516 LiDAR ground points (Fig. 6A), shows almost double our estimate in the north component but a

517 difference of only 3 mm in the east component, considering the mean value of the block.

518 Comparison of SJB1 GNSS station with the results with only LiDAR points on stable surfaces

519 (Fig. 6B) shows that the north component is smaller by ~13 mm and larger in the east component

520 by ~35 mm.

521
522 **Figure 6:** Horizontal displacements calculated with the ICP algorithm. **(A)** Horizontal displacements using ground
523 LiDAR points. **(B)** Horizontal displacements using stable surface LiDAR points. Each black arrow represents the
524 average displacement of an area of 2.25 km^2. Arrow directions represent the mean displacement direction, and the
525 length of the arrow represents the mean displacement magnitude. Ellipses show the error multiplied by 30 for
526 visualization, where East error represents the error in the east component and North error represents the error in the
527 north component. Red arrows are horizontal displacements using the rates from the GNSS stations for 19 years.
528 Base map imagery from QuickMapServices - QGIS (Map data ©2015 Google)

529 **4.3 Vertical displacement from LiDAR**

530 In this section, we show the results for vertical displacement using ICP and Vertical

531 DEM differencing. These two methodologies give us similar results: there is subsidence across

532 the complete region and subsidence is larger in the northern block than in the southern block.

533 Some regions show uplift mostly in the southern block and it is localized in areas where InSAR

534 time series have smaller rates (Figs. 4, 5, 7, 8). Results from ICP (Fig. 7A, 7B) show the

535 estimated vertical motion for an area of 2.25 km^2. In this case, subsidence increases from

536 southwest to northeast. ICP using LiDAR ground points (Fig. 7A) indicates that the uplift region

537 on the southern block is small while the northern block experienced greater subsidence.

538 With ICP with LiDAR points on stable surfaces, we detected that the uplift area is larger:

539 mostly across the southern block. Again, we estimate more subsidence in the northern block than

540 in the southern block (Fig. 7B). The errors for this experiment are larger compared to the ones

541 found using LiDAR ground points, although this was expected due to the lack of stable surfaces

542 in 1999 in comparison to the ones found in 2018.

543 In comparison to the SJB1 GNSS station, which shows a vertical motion between 1999-

544 2018 of -25.65 mm, the results using LiDAR ground points are almost four times larger than the

22

545 estimates from the station, and the results from the points of the stable surface are almost two

546 times larger. It is worth to remember that since the GNSS station is anchored at some unknown

547 depth, each tool may be measuring different processes.

548
549 **Figure 7:** Vertical displacement calculated from ICP algorithm. **(A)** Mean displacement using LiDAR ground
550 points. **(B)** Mean displacement using stable surfaces LiDAR points. **(C)** Margin of error of the results for (A). **(D)**
551 Margin of error of the results for (B). Each circle in A and B represents the mean displacement of an area of 2.25
552 km^2. Errors in C and D are calculated as the margin of error with respect to the mean. Rhombus are the vertical
553 displacement calculated using rate from the GNSS CORS stations for 19 years. Base map imagery from
554 QuickMapServices - QGIS (Map data ©2015 Google). Systematic errors are calculated as the average difference
555 between the fourth row from north to south of (A) and (B).

556 We calculated Vertical DEM differencing 1) without co-registration; 2) with co-

557 registration using ground points; and 3) with co-registration using points on stable surfaces.

558 Results without co-registration show mean displacements per block larger than 300 mm in the 19

559 years of analysis and more extreme values at individual locations; these values are not coherent

560 with other estimates nor the features in the area. We, therefore, only keep the results from co-

561 registered DEMs. We are just presenting the results for co-registration with ground points (Fig.

562 8) because these results and the ones co-registered with stable surface points present similar

23

563   patterns, but the sample of points here is larger for co-registration. The mean vertical

564   displacement for the northern block is -211.86 mm and for the southern block it is -133.09 mm.

565   Errors are found in Table 2. For this analysis the errors (MOE) are small due to the large number

566   of pixels on each block. These results show again more subsidence in the northern block than in

567   the southern block. Empty pixels in Figure 8 do not have results because there are water bodies,

568   high vegetation density, or the values were below the propagated error for each subarea of 2.25

569   km^2. Insets show areas of interest for the discussion section.

570
571   **Figure 8:** Vertical displacements calculated from Vertical DEM differencing. **(A)** Vertical displacements calculated
572   the co-registered DEM using results from ground points. **(B, C, D)** Some areas of interest discussed in the text.

573   All our estimates and main statistics are summarized in Table 2. These values are

574   averaged estimates for the whole block calculated using the results in that area, rather than

575   individual locations. This table does not include the residual systematic errors that may affect the

576   data for InSAR and LiDAR (Section 3.5). The former errors may be considered when looking at

577   individual locations.

578   **Table 2:** Main statistics per block for each tool. MOE stands for Margin of Error. Numbers marked with a * refer to
579   values derived from the estimates. These numbers do not have an estimated error and are for comparison purposes.
580   All the values are in NAD83. The InSAR displacements correspond just to the period indicated in the column Time
581   Span. The LOS rates for the GNSS stations are the projections of the rates using the parameters for each satellite.

5 Discussion

5.1 InSAR time series and LiDAR differencing measurements

We created time series with the PSI method using EnviSAT data between 2004 and 2010 and Sentinel-1 data acquired between 2017 and 2020. The rates and displacements calculated with this method are presented in the LOS direction. We are aware that there are significant horizontal displacements in the study area because the two GNSS stations and LiDAR-ICP results show displacements towards the north and east directions (Fig. 6). Owing to the horizontal displacements, we cannot isolate vertical displacements from InSAR because we only have one geometry for the SAR acquisitions, but we can compare the observations in the LOS direction to the vertical results from LiDAR (Zhong et al., 2022). PSI uses persistent scatterers on the surface to estimate their deformation, making this methodology appropriate for urban areas such as Baton Rouge (e.g., Ferretti et al., 2004). One must be cautious, however, with the interpretation of these results because they incorporate the signal of all the processes affecting the base of the persistent scatterer (e.g., Crosetto et al., 2016). One of the processes that may shape the results from the InSAR time series is the seasonal variations from the hydrological cycle (Li et al., 2020); for both datasets, most of the images were acquired during dry periods between October to April (Table S1). Then, if there is any elastic deformation caused by seasonal changes in water mass, it would appear more positive than negative due to the acquire dates of our images. Seasonal loading may increase the rates (Figs. 4, 5). If the rates are influenced by seasonal rebound, then subsidence may be larger than the rates reported with InSAR time series, based on comparison to hydrological models (e.g., Puskas et al., 2017; Chen et al., 2023).

605   The two LiDAR surveys used here were acquired over similar seasonal conditions. Then,

606   ICP and LiDAR differencing probably are measuring net changes between the surveys with little

607   impact of the seasonal cycles, although uncertainties must be considered for individual locations.

608   The results are more affected by the LiDAR point cloud with the worst resolution: the 1999

609   survey.

610   One of the advantages of using LiDAR data is that it allows one to separate the information

611   into surfaces of interest such as ground points and stable surfaces. We used this approach (Fig. 6

612   and 7) to estimate the displacement in the three components of surfaces that are at different

613   elevations or anchored in the subsurface. Just as InSAR, these methods measure signals of all the

614   processes that affect the base of the point. Here we take advantage of the spatial resolution of

615   LiDAR and averaged pixels to improve the results that can be affected by the low vertical

616   accuracy of the 1999 survey. With LiDAR we estimate the vertical and horizontal components of

617   displacement between the two surveys using ICP, which goes a step further than just the

618   estimates of vertical motion taken by Zhong et al. (2022). ICP estimates indicate that most of the

619   horizontal motion is towards the east in both blocks (Fig. 6), agreeing with the GNSS stations in

620   the area. Nevertheless, the horizontal displacements estimated with stable ground points (Fig.

621   6B) have more variations and seem to indicate more motion towards the north in comparison to

622   the ones estimated with ground LiDAR points, particularly near the eastern segment of the BRF

623   (Fig. 6). It is worth noting that the difference between the results from ground and stable LiDAR

624   points may indicate anomalies near the fault segment at different depths, but also may be caused

625   by the lack of stable surfaces in some areas in 1999 before rapid urban growth between 2005-

626   2010 (Supplemental Material – gif 1). The sharp change between the results using LiDAR

627   ground and stable points in the northern block (Fig. 7) may be caused by residual systematic

628   errors left after co-registration of the surveys (Section 3.6). This area marks the edge between

629   files from the 2018 point cloud. Systematic errors similar to the ones observed here have been

630   reported in previous research with topographic LiDAR data (e.g., Anderson, 2019).

631   **5.2 Comparison of LiDAR differencing, InSAR time series and GNSS records**

632   LiDAR results, ICP and differencing all indicate that the northern block is subsiding

633   faster than the southern block with respect to the 1LSU GNSS station. The InSAR time series

634   also indicates that the northern block is moving away from the satellite faster than the southern

635   block. It is, therefore, reasonable to assume that the vertical motion is dominating the

636 measurements, and it is very likely that the north component is negligible (e.g., Samieie-
637 Esfahany et al., 2010). From InSAR measurements, it is possible to see that the BRF serves as a
638 boundary between the areas of rapid and slow subsidence (Fig. 4 and 5). This behavior, however,
639 contradicts the long-term displacement of the down-to-south normal fault from seismic imaging
640 (e.g., Fig. 1).
641 The mean vertical rates from ICP vary between -8.4 to -5 mm/y in the northern block and
642 -5.1 to -2.4 mm/y in the southern block. Sentinel-1 rates in the LOS direction are larger than the
643 ICP vertical rates by ~5 mm/y in both blocks. We can, therefore, infer that the results are not just
644 comparable in magnitude but consistent, and that the northern block is subsiding faster than the
645 southern block.
646 In the southern block, there are two GNSS stations. We used the 1LSU station to tie the
647 results and SJB1 for comparison. These stations show that the southern block is subsiding and
648 moving horizontally E-NE in the NAD83 reference frame. This motion agrees with the direction
649 of the ICP results. The E-NE horizontal motion from the GNSS stations and ICP is likely due to
650 the definition of the NAD83 reference frame with plate fixed as indicated by horizontal velocity
651 models for North America (e.g., Snay et al., 2013; Robin et al., 2020). These results also suggest
652 shallow vertical slip rather than rotational slip along the BRF.
653 The velocity from Sentinel-1 InSAR time series on the building hosting SJB1 ranges
654 between -9 to -12 mm/y in the LOS direction, while SJB1 has a velocity of -8.40 mm/y (Fig. 4).
655 This difference can be caused by the length of the time series of each case; SJB1 rate is
656 calculated with data since 2010 while InSAR only covers 2017-2020. Changes in the station may
657 also play a role, but still, there is agreement among all the three tools. The two nearby GNSS
658 stations have different vertical motion rates (Section 2.4, Table 2; Fig. S3). The difference in
659 amplitude may appear as uncertainty in the InSAR data after tying to GNSS, whereas it is most
660 likely a local geological effect caused by the local response to groundwater changes. SJB1's
661 magnitude is better replicated by the results with stable LiDAR points (Fig. 7 and Table 2).

5.3 Relation with anthropogenic activities

663 Results from LiDAR differencing provide good estimates to detect trends of changes in
664 small areas due to their high spatial resolution. These results show the spatial trends of the
665 complete study area and the changes caused by human construction. For instance, the

28

666 construction of the FedEx facility in 2014, the Ochsner Medical Complex in 2017, the Woman's

667 hospital in 2010, and some new home complexes between 2006-2017 are seen in Figures 8C and

668 8D. Although these changes are visible with LiDAR, we consider that urban growth and new

669 constructions are not the main factors decelerating the rates in the southern block, or accelerating

670 them in the northern block, because urban growth has occurred across Baton Rouge

671 (Supplemental Material – gif, Fig. S6). There are multiple examples of construction with similar

672 characteristics in the northern block that do not affect the general spatial trend of the fault block

673 (Fig. S6). The 2000, 2010, and 2020 censuses indicate that the city's population has increased by

674 almost 10% (~44.000 new habitants) with most of this increase occurring during the first decade

675 and soon after Katrina (U.S. Census Bureau, 2003; 2012; 2021). The areas in the southern block

676 with smaller rates are recorded in LiDAR ICP, vertical DEM differencing, and in both InSAR

677 time series.

678 During the study period 2034 water wells were active, with 592 of them extracting water

679 for multiple purposes (Fig 9, Table 1). The remaining wells monitored groundwater quality and

680 level mostly near industrial wells, close to areas of injection or oil and extraction, and near the

681 western and middle segments of the BRF. Most of the groundwater in East Baton Rouge is used

682 for industrial and public supply. These uses are recognized to cause most of the decline of the

683 groundwater levels in the region and saline intrusions near the BRF (Tomaszewski et al., 2002;

684 Anderson et al., 2013). Groundwater studies indicate the aquifers in the northern block recharge

685 from infiltration in areas north of the DSF (Tomaszewski et al., 2002; Vahdat-Aboueshagh and

686 Tsai 2021), while the aquifers in the southern block are filled mostly with saline water from the

687 GOM (Fig. 1). It is known that groundwater withdrawal in the Baton Rouge district surpasses

688 recharge, causing the decline in groundwater levels (White, 2017). There are more water wells in

689 the northern block than in the southern block for almost all uses due to the salinity charge (Fig.

690 9A). Also, most wells are at deeper depths in the northern block (Fig. 9B). The mean depth for

691 industrial and public supply wells is between 400-500 m, probably reaching the deeper sand

692 layers (1500 and 2000-ft sands). These aquifers have been greatly affected by pumping water

693 (Tomaszewski et al., 2002; Nasreen, 2003; Elshall et al., 2013), and have developed cones of

694 depression (Chen et al., 2023). On the other hand, the southern block has fewer water wells

695 extracting water, which is more saline, and are at shallower depths. Our results support the

696 hypothesis that the northern block is part of a regional depression cone caused by water

697 extraction and observed in previous groundwater models (e.g., Chen et al., 2023). This may

698 explain the general trend of subsidence displacements increasing from south to north with
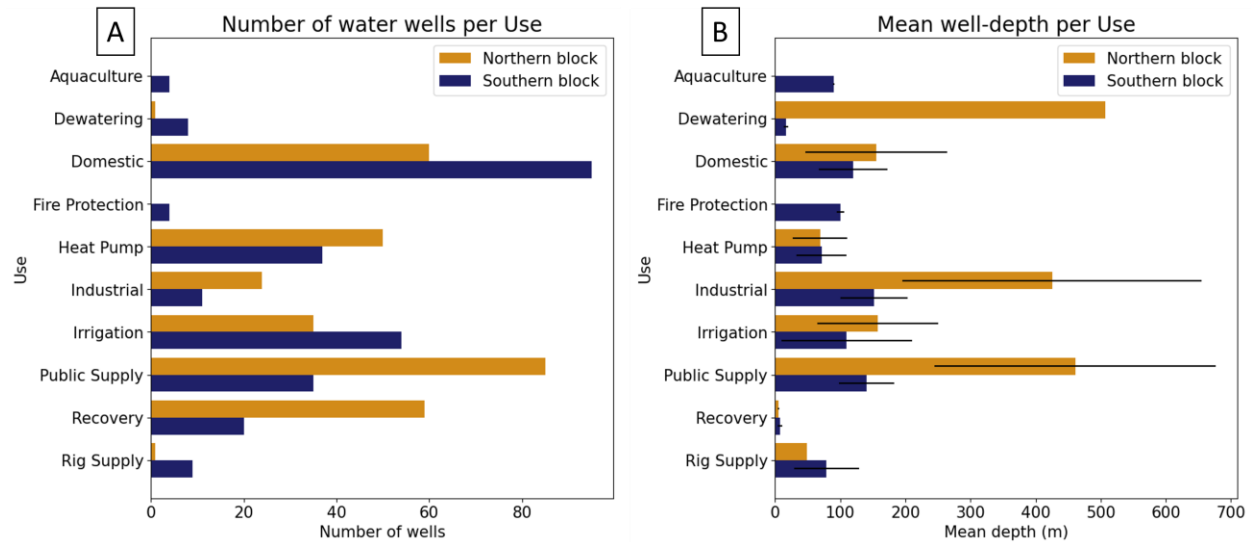

699 LiDAR and in the LOS direction with InSAR time series.

700
701 **Figure 9:** Water well statistics per block in the study area. **(A)** Number of wells per use. **(B)** Mean depth of water
702 wells per use. Lines indicate standard deviation of the well depth values. Well data from the Louisiana Department
703 of Natural Resources (SONRIS), (n.d.).

704
705 The relationship between groundwater withdrawal and subsidence is known and supported

706 by several studies globally (e.g., Guzy and Malinowska, 2020; Fiaschi and Wdowinski, 2020).

707 Jones et al., (2016) concluded that groundwater withdrawal caused subsidence in the Michoud

708 area in New Orleans. They found that areas around chemical plants or refinery facilities with

709 water wells have larger subsidence rates than areas without these wells. The area with largest

710 subsidence in our study area was detected with LiDAR methods (Fig. 7 and 8B), while in InSAR

711 time series it is masked by dense vegetation. This region does not have water wells, but there are

712 15 water wells that were active during the study period within a radius of 2 km, seven of which

713 are of domestic use at the north and east, five for public supply in the west and south, three for

714 irrigation in the west direction (Fig. S7). Another factor that should not be ignored is the

715 proximity to the Comite river at the eastern edge of the study area (Fig. 3) and its interaction

716 with the aquifers in this area. Chen et al. (2023) argue that the Comite river does not have

717 important interactions with the Southern Hills aquifer system, although locally this area remains

718 an open question.

719

720   Figures 8C and 8D show the areas with the smallest subsidence displacements in the study

721   area. These areas have most of the injection and oil/gas extraction wells (Fig. 2, S4, Table 1).

722   Ten of these wells injected saline waters at depths between 1445-3155 m. The other injection

723   wells are at ~15 m depth and are not included in these areas. Multiple studies have shown that

724   injection of fluids can increase pore pressure at depth which can diffuse and cause local uplift

725   (e.g., Teatini et al., 2011; Anderson et al., 2013; Shirzaei et al., 2016). Shirzaei et al., (2016)

726   related injection of fluids with large surface displacement and earthquakes in Texas. For their

727   model they calculated a volume change of 700.000 m^3/y which is close to the injection volume

728   of their area. Consequently, an increase in subsurface pressure caused by injection can be an

729   explanation for the slower displacements and rates in the southern block (e.g., Fig, 4C point P6).

730   We compare the depth and injected volume of the injection wells with our results (Fig. 10) to see

731   if there is any evidence of change of the surface that could be related to them. Our study area

732   does not have a total injection above 300,000 m^3/y during the study period (Fig. 10), suggesting

733   that pressures are not yet large enough to induce earthquakes.

734   One interesting example of the possible signals of injection are the wells identified as 971098

735   and 188322 (Fig. 10). They are separated by ~ 200 m and both injected a similar volume of

736   saline water. The first one injected water before 2008, while the second experienced fluid

737   injection between 2011 and 2019. Besides the period of injection, these two wells differ in the

738   depth of injection: Well 971098 bottoms at ~1500 m whereas 188322 bottoms at ~3000 m. The

739   two injection depths fill different sand bodies, but the shallower well is expected to contribute

740   more to the observed relative uplift of the southern block; there is not a strong signal from the

741   deeper well in the Sentinel-1 dataset. This was expected due to the disposal depth of the wells.

742   Another example is the four wells in the western part of the study area (Fig. 10). The distance

743   among these is less than 1 km. The depth of these wells varies between ~1500 to ~3000 m. The

744   complete area seems to be moving at slower rates than the northern block, but it is not possible to

745   disentangle the signal caused by each injection well. Our observations indicate that the BRF may

746   be acting as a barrier preventing flow of the injected fluids to the northern block (e.g., Shirzaei et

747   al., 2016).

748   We perform a similar comparison with the oil and gas wells (Figs. S4, S8). All of these wells

749   have bottom hole depths deeper than 1700 m, and most are near the injection wells which are at

750   shallower depths. It is not possible to say whether these wells are causing any change in our

751   results, and therefore we cannot conclude that oil and gas extraction during the study period
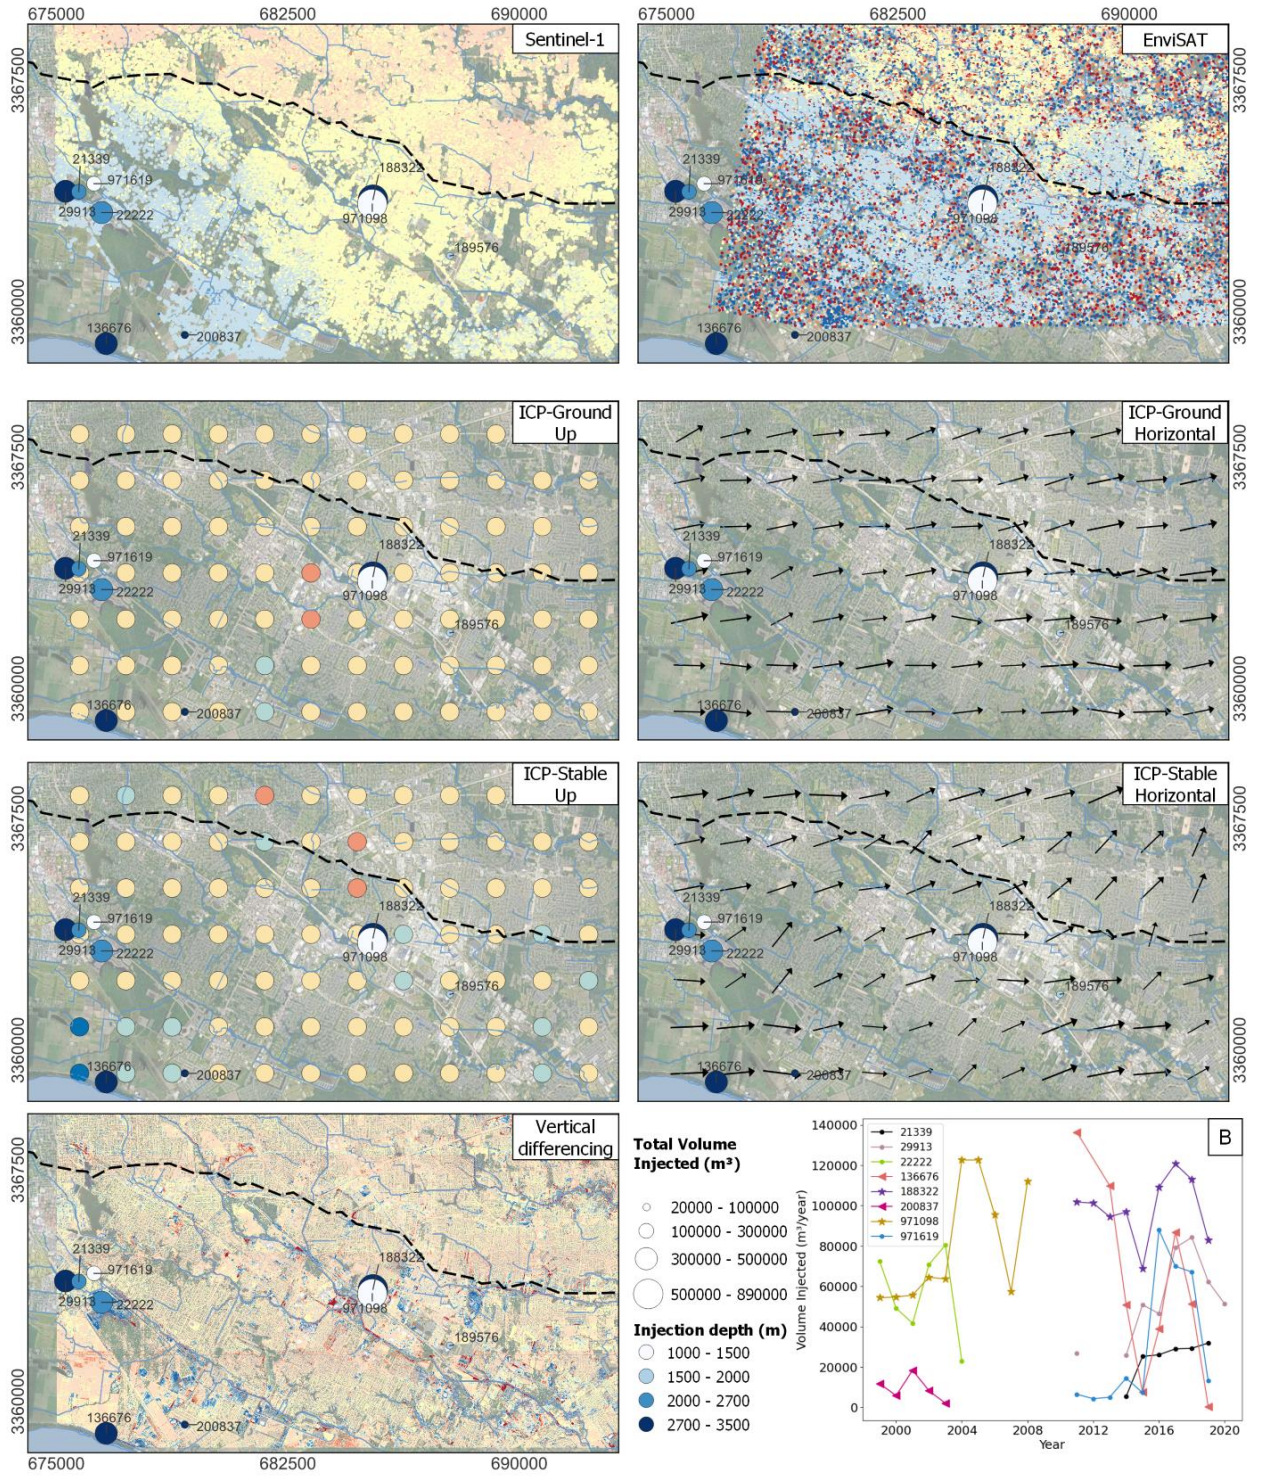

752   caused any change on the surface.

753

Figure 10: Injection volumes and depth shown in all our results. **B)** Time series of volumes injected by each well in the study area between 1999 and 2020.

756 **5.4 Geological factors**

757   The study area has multiple factors that may contribute to vertical crustal movement that are

758 difficult to deconvolve, but sediment compaction is minimal. Our results from InSAR time series

759 and LiDAR show that the entire area is subsiding, but that the BRF marks the boundary between

760 faster and slower subsiding areas (Figs 4-8). These results agree with groundwater models of the

761 region. The sharp change in vertical crustal movement along some sectors of the BRF suggests

762 that BRF remains a hydrological divide, but we cannot determine whether parts or all the fault

763 slipped episodically or continuously between 1999 and 2020. The rates that we determined

764 (Table 2) are two orders of magnitude larger than the time-averaged fault slip rate from Shen et

765 al. (2017) (~ -0.02 mm/y) and are comparable or larger than the ~3 mm/y from Hopkins et al.,

766 (2021) for some segments of BRF. The correlation of changes in vertical crustal motions with

767 injection and water wells indicates that anthropogenic activities have increased BRF slip rates,

768 but we cannot conclude much about the DSF due to the lack of information in the area.

769   We present four examples of individual structures' motion along the BRF (Fig. S9;

770 Supplemental material - T2). It is important to highlight the examples in the center area of the

771 fault that show more motion than those near the eastern and western limits, although the

772 foundations of examples are unknown and, in some cases, the number of PSIs is very small. We

773 recommend further investigation of individual structures with InSAR time series and/or ground

774 leveling campaigns.

775   Horizontal displacement from ICP in the eastern portion of the BRF shows an apparent

776 change of direction (Fig 6). Despite the large uncertainties, this can be an area of future research

777 because 1) the Nesser and Siegen oil fields are nearby in the southern block and were exploited

778 during the study period, 2) in August of 2016, the Amite River (Fig. 3) flooded affecting the

779 eastern part of the study area which may influence the time-averaged estimates in the area.

780 **5.5 Future Implications**

781   Vertical crustal motion occurred in the Baton Rouge sector of the GOM passive margin since

782 1999, as detected here with InSAR and LiDAR methods, and corroborated by sparse GNSS data.

783 These vertical crustal movements may be an indicator of groundwater storage changes and

784 recharge characteristics for the aquifers under the study area. These motions may also indicate

785 how injection at shallow depths is deforming the surface. The BRF zone serves as a boundary

786 between two differentially subsiding blocks, indicating that it may also separate distinct

787 hydrographic domains, and that it localizes differential motion. Hydrological studies indicate

788 that the aquifers in the northern block are more affected by groundwater withdrawal than those in

789 the south (e.g., Elshall et al., 2013). The subsidence rates in the northern block increase from the

790 BRF towards the DSF, and in the southern block subsidence increases south of the BRF, where

791 saline water infiltrates sand bodies and where saline wastewater is injected (Nasreen, 2003;

792 Elshall et al., 2013; White, 2017). Our results agree with recent groundwater change models of

793 Chen et al. (2023). They show that the average groundwater levels between 2004 and 2020 were

794 low (-10 to -20 m) in Baton Rouge between the BRF and the DSF. This area is part of the local

795 cone of depression caused by the large water extraction of deep aquifers at 400-900 m depth. Our

796 results in the northern block may be the surface expression of the changes in groundwater

797 storage (i.e., the cone of depression) caused by the decline of groundwater levels showed on

798 Chen et al., (2023).

799 East Baton Rouge is one of the most populated parishes in Louisiana and likely its population

800 will grow as it has done it in the last 20 years (U.S. Census Bureau, 2003; 2012; 2021). Besides,

801 due to climate changes expected for the ongoing century in the GOM (Pendleton et al., 2010;

802 Frederikse et al., 2020; Dangendorf et al., 2023), coastal retreat from regions vulnerable to storm

803 surge and wind damage from hurricanes will continue to drive population growth (e.g., Qiang

804 and Lam, 2016) as has happened before (Sastry, 2009). Simultaneously, as the population grows,

805 water consumption likely will increase. Considering vertical surface changes as a proxy for

806 groundwater level and storage changes, it is important to protect the aquifers underlying the area

807 from saline water intrusions and groundwater level decline. These actions will also protect the

808 surface from non-natural changes.

809 There are many wells whose purpose is to monitor local groundwater, but just two GNSS

810 stations to study surface elevation changes; they are wholly inadequate to track BRF movement.

811 The localized fault slip along the BRF and differential ground subsidence motivates continuous

812 monitoring at local and regional scales to track surface elevation changes associated with fluid

813 extraction and injection.

814   **6 Conclusions**

815   This study presents a detailed regional panorama of the relationship between injection and

816   extraction of fluids and vertical and horizontal surface displacements. We also show how

817   geodetic methods can be used to estimate vertical and horizontal displacements in areas with

818   slow motions for the first-time using LiDAR data with the ICP algorithm. InSAR time series

819   with PSI is a suitable method for urban areas such as Baton Rouge and shows similar results to

820   LiDAR in the LOS direction after GNSS corrections. We verify our results using ground

821   measurements from permanent GNSS stations. The agreement of the results from the three

822   datasets on the same reference system offers insight into the reliability of LiDAR to estimate

823   vertical and horizontal motion. We reiterate the need for more GNSS stations in the area,

824   particularly in the northern block, to adequately track the motion of the BRF and to better

825   constrain the results from other geodetic methods.

826   We selected East Baton Rouge as the study area because the deformation signal caused by

827   fault slip and anthropogenic activities should control vertical ground motion. Our results show

828   that the entire area is subsiding, but subsidence reverses the long-term, down-to-the-south

829   displacement. We observe that the BRF divides the study area into two different regions of

830   mostly human-controlled subsidence: 1) Subsidence in the northern block is likely controlled by

831   groundwater level changes caused by pumping and it is sinking faster than the southern block

832   showing a cone of depression. These results are supported by recent groundwater models. 2)

833   Subsidence in the southern block, which is influenced by the injection of fluids at shallow depths

834   that may be causing volumetric expansion and less water pumping. It is important to remember

835   that seasonal contributions can influence the results from InSAR time series, and it is something

836   to consider in future analysis. Horizontal motions estimate from ICP show that the area is

837   moving to the east with a small displacement to the north. This agrees with the estimates from

838   GNSS.

839   Considering the future climate change scenarios where population displacement and water

840   scarcity are likely, it is important to consider these observations for future city planning to ensure

841   the conservation and protection of the aquifers in the area, and to minimize the effects of saline

842   infiltrations through the BRF.

843

853 **Data Availability Statement**

854 LiDAR data from 1999 is stored and distributed by the Atlas: The Louisiana Statewide GIS

855 (https://maps.ga.lsu.edu/lidar2000/). LiDAR data from 2018 is stored and distributed by the

856 USGS Server through The National Map Download Manager

857 (https://apps.nationalmap.gov/downloader/).

858 EnviSAT SAR images were retrieved from the Earth Observation Catalogue

859 (https://eocat.esa.int/sec/#data-services-area). Sentinel-1 SAR images from the Copernicus Open

860 Access Hub (https://scihub.copernicus.eu/dhus/#/home). Both property of the European Space

861 Agency.

862 GNSS information was processed by the Nevada Geodetic Laboratory (Blewitt et al., 2018;

863 http://geodesy.unr.edu/NGLStationPages/gpsnetmap/GPSNetMap.html).

864 Data from water, injection, and extraction wells is stored in the Strategic Online Natural

865 Resources Information System property of the Louisiana Department of Natural Resources

866 (http://sonris-www.dnr.state.la.us/gis/agsweb/IE/JSViewer/index.html?TemplateID=181).

867 LiDAR and InSAR results are available in a data repository (Hurtado-Pulido et al., 2023).

868

869 **Software Availability Statement**

870 LiDAR data was filtered to create stable surface clouds and DEMs were created using the Point

871 Data Abstraction Library (PDAL, 2018). The ICP algorithm was run using the MATLAB code

872 created by Scott et al. (2020) that uses the LIBICP software (Geiger et al, 2012). The

873 Geomorphic Change Detection software (GCD) was used to create the DEMs of Differences

874 (Wheaton et al., 2010). InSAR time series were processed using SARscape (2021) software.

875   Spatial analysis and maps were done with QGIS v. 3.18 (2018). Figures were done using

876   Matplotlib on Python (Hunter, 2007).
