ABSTRACT

We assess the potential implementation of earthquake early warning (EEW) across Europe, where there is a clear need to take effective measures for mitigating seismic risk. EEW systems consist of seismic networks and mathematical models/algorithms capable of real-time data telemetry that alert stakeholders (e.g., civil-protection authorities, the public), to an earthquake's nucleation seconds to minutes before strong shaking occurs at target sites. During this time, actions can be taken to significantly decrease detrimental impacts. We investigate distributions of EEW warning times available across various parts of the Euro-Mediterranean region, based on seismicity models and seismic network density. We then determine the risk-reduction potential of these times, by defining their spatial relationship with exposure, event-dependent vulnerability, and an alert accuracy proxy, using well-established risk-prediction tools from earthquake engineering. The results are quantitative EEW feasibility maps, which demonstrate that EEW could be an effective risk-mitigation tool for a significant portion of Europe.

Introduction

Earthquake early warning (EEW) systems are a relatively recent innovation in earthquake-induced disaster risk reduction and resilience promotion¹. They consist of seismic sensor networks and mathematical models/algorithms that are designed to process and disseminate real-time information about ongoing earthquakes. The resulting alert messages enable various stakeholders (e.g., individuals, communities, governments, businesses) located at distance to take timely measures for reducing the likelihood of damage or loss before strong shaking reaches them². Examples of important risk-mitigation actions that can be taken in the short warning time provided by EEW systems (typically seconds to minutes) include: (1) Performing “drop, cover and hold on” (DCHO)³ or moving to a safer location (either within a building or outside), to avoid injuries; (2) slowing down high-speed trains, to reduce accidents⁴; (3) shutting off gas pipelines, to prevent fires⁵; and (4) switching signals to stop vehicles from entering vulnerable infrastructure components (such as bridges), to avoid fatalities⁶. This list accounts for merely a small number of the vast array of critical applications that can benefit from EEW⁷.

The process of EEW typically involves up to five main steps: (1) Detecting an earthquake, (2) estimating its location; (3) estimating its magnitude; (4) estimating the ground-motion at target sites; and (5) using all of the information collected to decide whether (or not) to trigger an alarm. EEW systems may be broadly categorised as “regional”, “on-site” (or “hybrid”), depending on their approach to the first three steps mentioned above. This study exclusively focuses on regional systems, which consist of seismic station networks installed within the expected epicentral/high seismicity area that record the necessary information for estimating the parameters of Steps 1, 2 and 3. The source parameter estimates of Steps 2 and 3 are then used to predict ground shaking (Step 4) at target sites located further away from the fault rupture⁸.

Regional EEW systems are presently operating in nine countries (including USA, Mexico, and Japan), and have been tested for application in a further 13⁹. This paper investigates the feasibility of their application in the Euro-Mediterranean area, where there is a strong need to develop effective measures for mitigating seismic risk¹⁰; this is underlined by the fact that the average annual European GDP affected by earthquakes exceeds \$20 billion¹¹. In addition, the only European countries with current operational EEW systems are Romania¹² and Turkey¹³. In particular, we focus on EEW warning time (i.e., the time between the delivery of an EEW alert and the arrival of strong shaking at target sites). We compute probabilistic distributions of warning times available for various seismicity scenarios in high-hazard areas across the continent, using a sophisticated travel-time algorithm incorporating wave propagation physics. We also explicitly quantify the risk-mitigation potential of these times for specific magnitude events, by establishing their spatial relationship with values of proxy measures for seismic vulnerability,

exposure, and alert accuracy.

A number of studies have previously explored the feasibility/potential of EEW in different parts of the world, including France¹⁴, Italy^{15–17}, Spain¹⁸, Portugal¹⁹, Turkey²⁰, Japan²¹, California^{22,23}, Hawaii²⁴, the New Madrid Seismic Zone²⁵, and Kyrgyzstan²⁶. This work significantly advances the state-of-the-art established by the aforementioned studies for a number of reasons. It examines EEW feasibility on a much larger (i.e., continental level) scale by combining EEW methods, models, and tools in a harmonised framework across Europe. Furthermore, we introduce a novel feasibility metric that enables identification of priority regions for further, more refined EEW feasibility analyses and/or actual investment in EEW systems for targeted end users. This study therefore offers a unique trans-national perspective on the potential of EEW that is highly relevant for intergovernmental stakeholders, such as the International Search and Rescue Advisory Group (INSARAG) of the United Nations²⁷. It also provides valuable new insights on the possible benefits/limitations of EEW for regions (e.g., Iceland and Georgia) that have not recently experienced large earthquakes, but are likely to do so in the future.

Results

European Seismic Station Density

We conduct a preliminary feasibility study for EEW across the European region, by considering the availability of its most fundamental component, i.e., seismic station networks on which the early seismic signals could be detected/recorded for rapid event characterisation. Figure 1a displays a map of European seismic stations (2,880 stations in total). It can be seen from Figure 1b that approximately 55% of interstation distances are less than 20 km and almost all interstation distances are within 100 km.

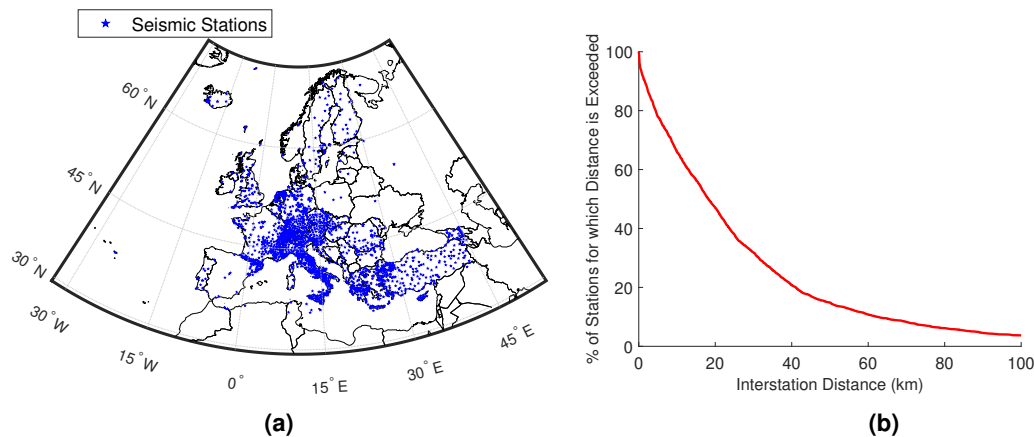

Figure 1

Lead-Time Mapping for High Hazard Areas

We now focus on crustal point sources associated with large seismic hazard of engineering significance, which we define as those for which the event with a recurrence interval of 500 years is at least M_w 6.5 (see Figure 2a and **Methods** section). For each of these area sources, we calculate potential lead times (i.e., warning times that would be provided by EEW before shaking occurs) at target sites where the predicted median peak ground acceleration (PGA) associated with 500-year recurrence-interval events exceeds 0.05 g (see Figure 2b and **Methods** section), which is a commonly used threshold value for strong earthquake shaking in several engineering applications, including seismic design aimed at life-safety performance^{28–30}. Figure 3 displays histograms of lead times computed at selected target sites in three major capital cities covered by the study area, i.e., Rome, Istanbul, and Athens, due to the area sources that comply with the previously outlined criteria. It can be seen that the majority of lead times are positive for all three sites. The median lead times for the sites are 4.0 seconds (Rome), 6.5 seconds (Istanbul), and 5.8 seconds (Athens), while the standard deviations of the times (in the same order) are 3.6, 5.7, and 5.0; these uncertainties are significant, reflecting the large variation in source-to-site distances for a given site.

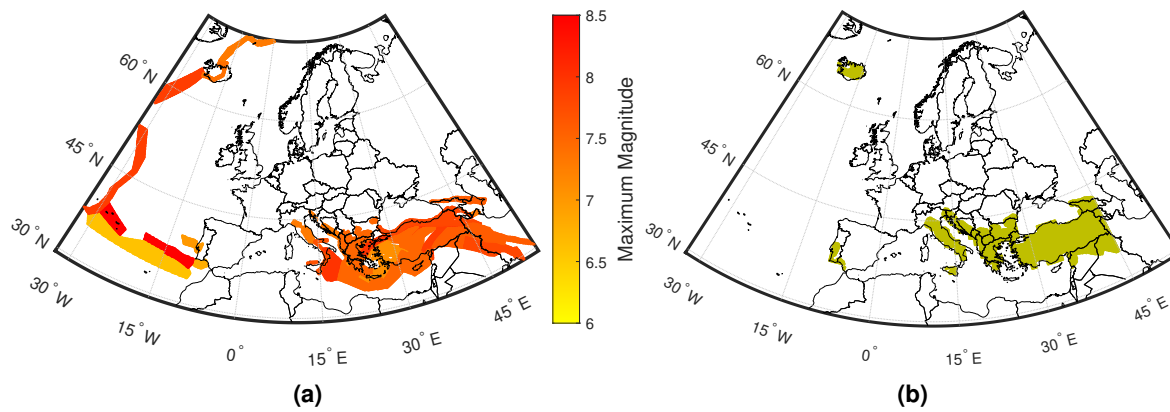

Figure 2

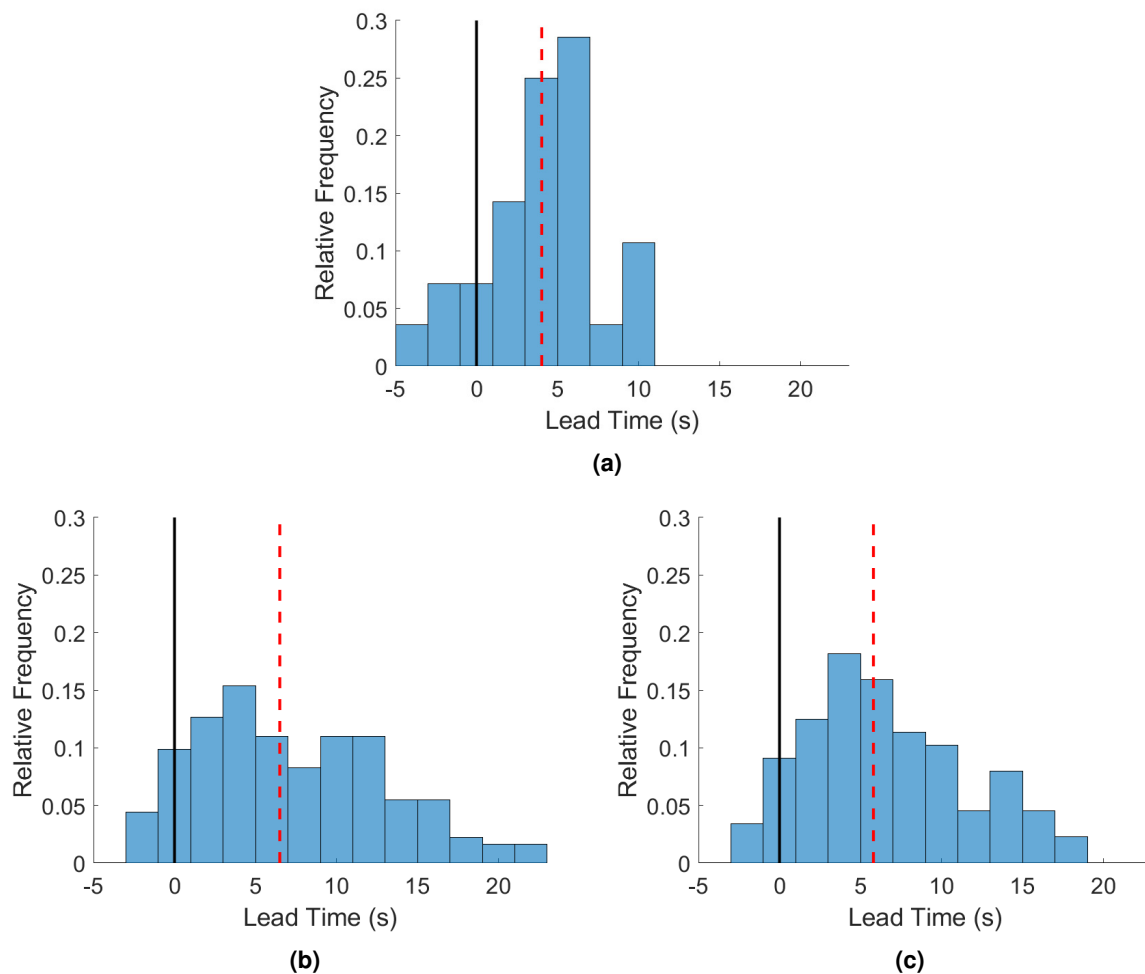

Figure 3

Figure 4 contains maps displaying the following three summary statistics for all affected target sites across the continent: (1) minimum lead time (i.e., “worst case scenario”); (2) median lead time; and (3) maximum lead time (i.e., “best case scenario”). Note that negative lead times correspond to blind zones, where no warning is received before strong shaking occurs. Of all target sites examined, 7% have positive minimum lead times (<1% greater than 10 seconds, 2% between 5 and 10 seconds, and 5% less than 5 seconds); 46% have positive median lead times (2% greater than 10 seconds, 9% between 5 and 10 seconds, and 5% less than 5 seconds); and 5% less than 5 seconds); 46% have positive median lead times (2% greater than 10 seconds, 9% between 5 and 10 seconds, and 5% less than 5 seconds); and 5% less than 5 seconds).

35% less than 5 seconds); and 91% have positive maximum lead times (44% greater than 10 seconds, 30% between 5 and 10 seconds, and 17% less than 5 seconds). The maximum lead time achieved across all target sites examined is 34.0 seconds (near Bafra, northern Turkey). Countries containing target sites with the longest overall lead times are Iceland, Greece and Turkey, which are characterised by some of the strongest seismicity in Europe. On the other hand, countries containing target sites with the shortest overall lead times are Iraq, Georgia, and Russia. Table 1 provides a summary of potential risk-reducing actions that can be carried out for the various ranges of lead time investigated.

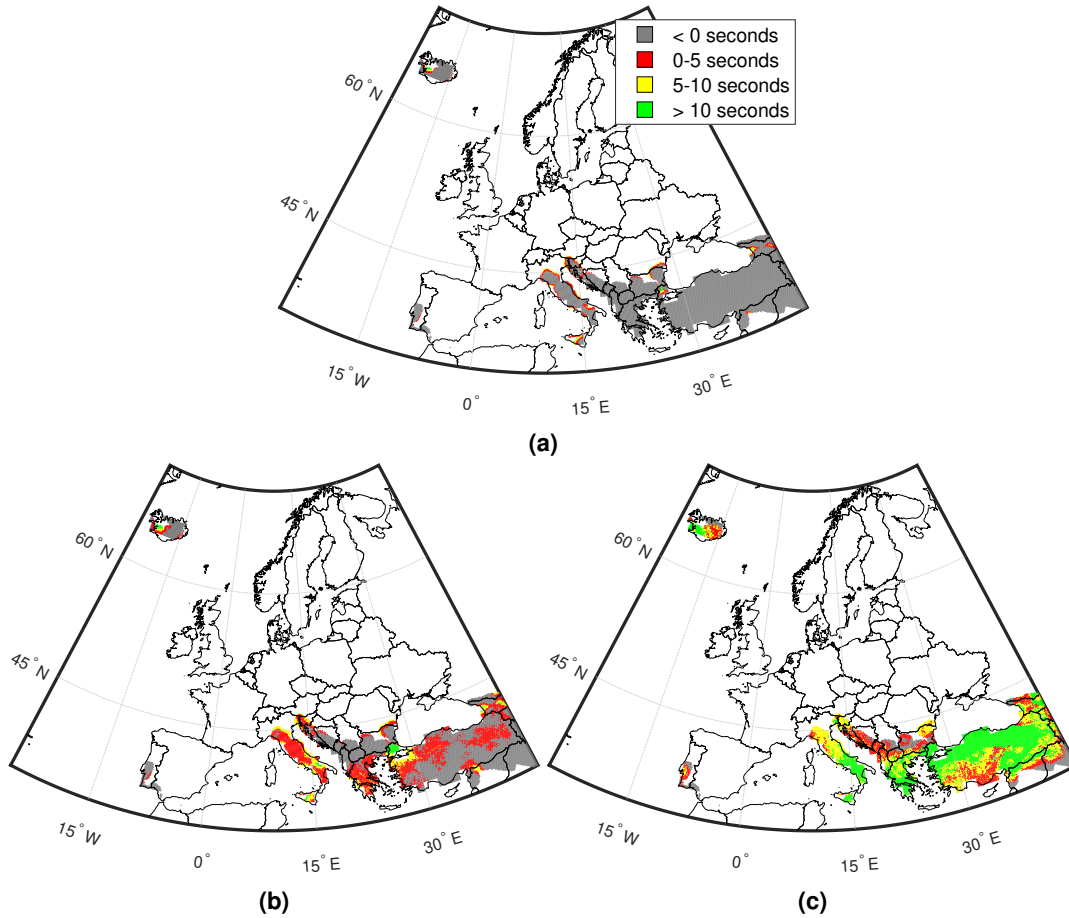

Figure 4

Benchmarking the Calculations

The lead-time maps presented in Figure 4 are computed using a complex travel-time algorithm explicitly accounting for the physics of seismic wave propagation³¹ (see **Methods** section). Many previous studies of EEW lead time and blind zone extent^{16,18,25,32–35} have adopted far more simplified approaches to the calculation of travel time, which only consider the arrival of direct p-waves (i.e., do not fully incorporate wave-motion physics) and may also only account for average values of wave velocities. We now benchmark the lead-time maps of Figure 4 (i.e., the “original case”) against those obtained using a simplistic travel time calculation, which is similar to the methods adopted in the aforementioned literature (see **Methods** section for details). The results of this benchmarking exercise are plotted in Figure 5.

The greatest discrepancies between the maps developed using the two travel-time models tend to occur for the largest absolute values of lead time in the original case. In general, the simplistic model results in higher lead times at target sites where the lead time is positive for the original case, and it results in lower lead times at sites where the original lead time is negative. 5% of minimum lead times, 16% of median lead times, and 64% of maximum lead times are over-estimated by at least one second when the simplistic travel-time model is used, whereas 13% of minimum lead times, 8% of median lead times, and 4% of maximum lead times are under-estimated by at least the same amount.

Secondly, we verify the adequacy of the resolution chosen for the lead-time map, by benchmarking the resulting times for Italy with those obtained using a finer seismic source/target site grid spacing (see **Methods** section). From a visual comparison of Figure 4 and 6, it can be concluded that there are no notable differences in the lead times obtained at both resolutions.

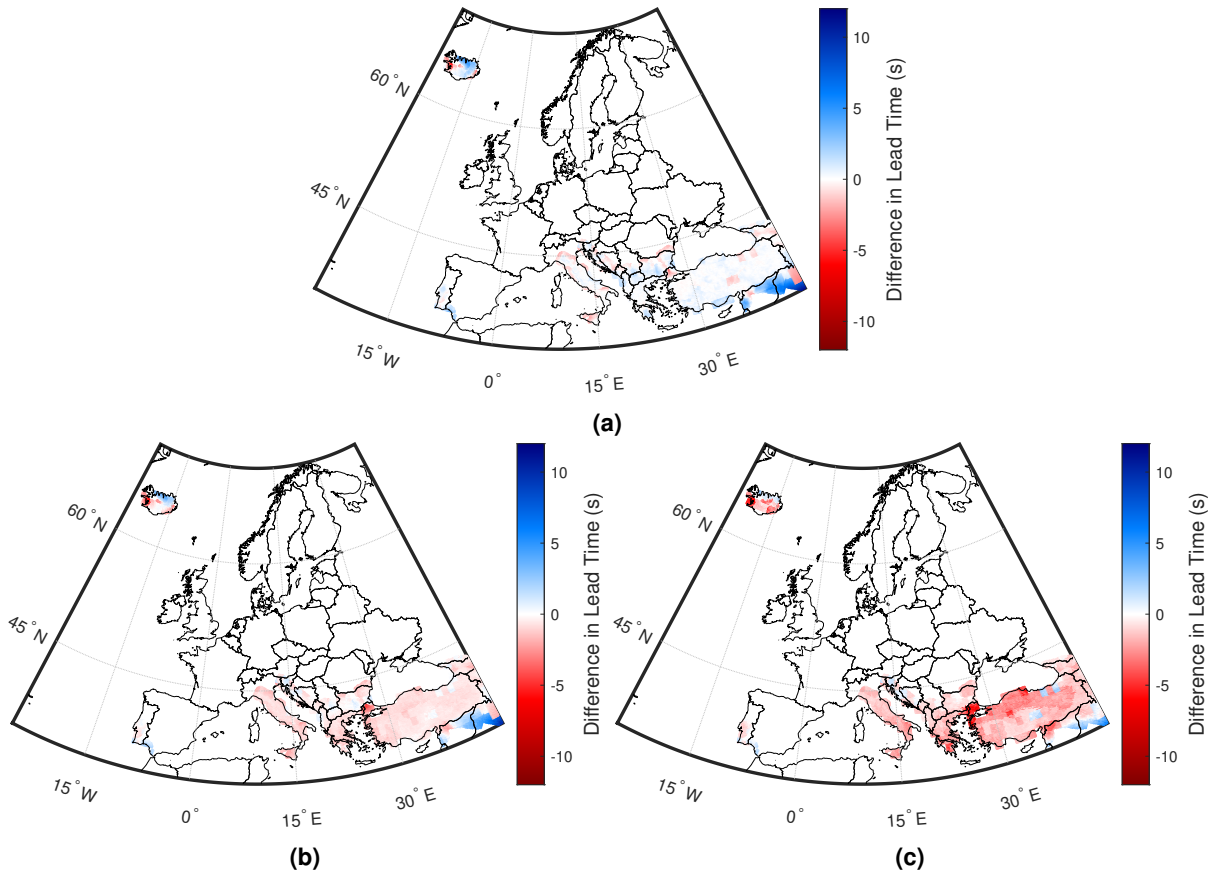

Figure 5

Therefore, the grid spacing of the European-wide map is deemed adequate.

Risk Quantification

We examine the risk-mitigation potential of the calculated lead times, by defining their spatial relationship with ambient (average day/night) population distributions and the average seismic intensity across all events with a recurrence interval of 500 years that produce a PGA greater than or equal to 0.05 g at the affected site (see **Methods** section for details). Population is an important consideration in seismic risk assessment³⁶ that often acts as a proxy for the exposure (i.e., the value at risk) of the built environment/assets in earthquake engineering and risk modelling applications³⁷. Seismic intensity, which describes the effect of earthquake ground shaking on the built environment and communities, is a well-established proxy for both damage³⁸ and vulnerability³⁹. We use the EMS-98 seismic intensity scale³⁹, which is specifically designed for European countries.

98% of the total ambient population surrounding the examined target sites are affected by average EMS-98 values between V (“Strong” e.g., top-heavy objects topple over) and VII (“Damaging” e.g., many objects fall from shelves and there is some wall damage). Figure 7 indicates that approximately 38% of the ambient population are affected by EMS-98 values between V and VI (“Slightly damaging” e.g., objects fall from walls and there is some damage to plaster), while approximately 60% are affected by values between VI and VII. 38% of the ambient population affected by average intensities between V and VI have maximum lead times greater than 10 seconds, while 10% have negative maximum lead times (i.e., they are located in the “blind zone”). 59% of this population have positive median lead times, and 18% have positive minimum lead times. 65% of the ambient population affected by average intensities between VI and VII have maximum lead times greater than 10 seconds, while 4% are located in the “blind zone”. 56% of this population have positive median lead times, and 1% have positive minimum lead times.

EEW Feasibility Calculation

We combine estimates of median lead time (L), average seismic intensity (I), and affected ambient population (P) into a single, novel metric of EEW feasibility, termed the EEW Relative Feasibility Index (see equation 4 of **Methods** section for details). Higher values of this index correspond to key characteristics that maximise the effectiveness of an EEW system³², i.e.:

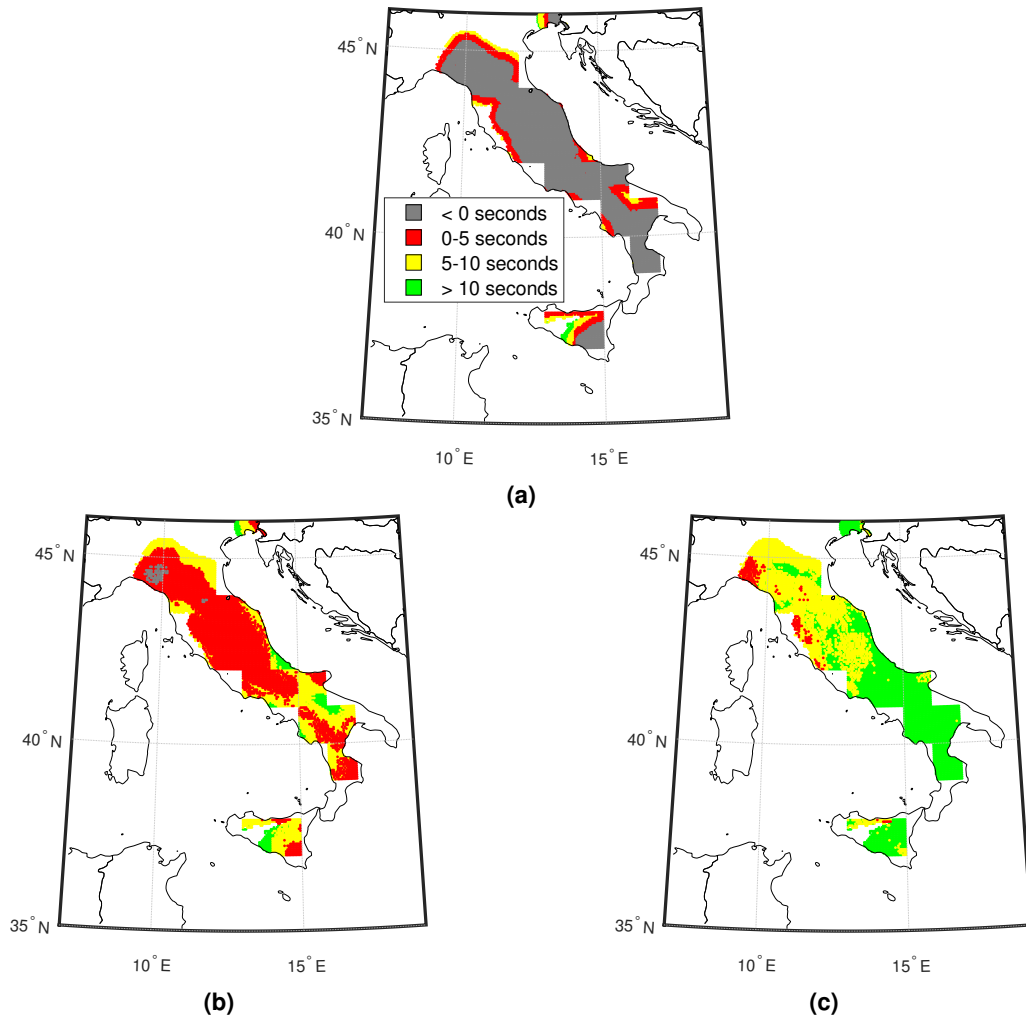

Figure 6

(1) longer lead times; (2) higher potential for shaking causing losses that can be avoided with EEW; and (3) larger affected populations. They therefore indicate greater EEW feasibility for a given target site.

It can be seen from equation 4 that the index accommodates a user-defined weight for each measurement, to account for stakeholder preferences and priorities. Figure 8 includes EEW Relative Feasibility Index mapping of all target sites with positive median lead time, for the equally-weighted case (i.e., $w_P = w_I = w_L = 0.333$) and for cases where one variable (e.g., lead time) is weighted three times more than the other two (e.g., $w_L = 0.6$, and $w_P = w_I = 0.2$). Also highlighted in each subplot are the fifty target sites with the largest index values for the corresponding case. For all cases, the countries containing sites with the fifty largest feasibility indices are Italy, Turkey, and Greece. However, both the locations and the number of sites per country differ between cases. Relative to the equally weighted case, target sites with the largest increase and decrease in feasibility index for the case where lead time is the most weighted variable are located in Iceland and Turkey respectively, target sites with the largest increase and decrease in this value for the case where seismic intensity is the most weighted variable are located in Turkey and Georgia respectively, and target sites with the largest increase and decrease in feasibility index for the case where population is the most weighted variable are both located in Turkey.

Finally, we investigate the impact of alert accuracy (i.e., the ability of the system not to miss or provide false warnings) on EEW feasibility. We specifically adopt the approach of Minson et al.²³, which examines the forecasting capability of EEW in terms of ground motion prediction accuracy for a set of known source parameters. We randomly sample PGA values at each site for a series of earthquakes across nearby sources, assuming that an alert is issued if the corresponding median predicted PGA exceeds 0.05 g. The relative feasibility indices of Figure 8a are then scaled by the relative proportion of correctly issued alerts to produce Figure 8e; see equations 5 and 6 of **Methods** section for details. It can be seen that alert accuracy has a significantly detrimental effect on the feasibility of some target sites, reducing indices by up to approximately 0.8. It causes the smallest

Figure 7

and largest feasibility decreases in Slovenia and Turkey, respectively. However, target sites with the largest feasibility are still located in Italy, Turkey, and Greece (along with Iceland). It is important to note that alert accuracy is highly dependent on the selected threshold. To demonstrate this, Figure 8f shows a summary of the proportion of different alert outcomes obtained across all sites considered in this study, as a function of the various alert thresholds examined in Minson et al.²³. In particular, it can be seen that the number of correct alerts decreases with increasing threshold. This trend was also observed for California data by Minson et al, who obtained similar alert outcome proportions to those in Figure 8f.

Discussion

This study has examined the feasibility of EEW for Europe. Our initial analysis examined the density of seismic station coverage across the continent. We found that over half (i.e., approximately 55%) of interstation distances are between 0 and 20 km, which corresponds with the distance range recommended for optimum EEW performance in previous work³². These findings are a preliminary signal that there is significant potential for operational EEW across the continent.

Our detailed feasibility analysis focused on Euro-Mediterranean regions affected by significant seismic hazard. Probabilistic distributions of EEW lead (warning) times were determined for target sites in these areas, by randomly varying the location of seismic sources in line with regional seismicity. Summary statistics of these times were then translated into maps, which give additional promising indications of the potential usefulness of EEW in Europe. For example, they show that almost half (i.e., 44%) of the examined target sites benefit from warning times in a “best case scenario” that are long enough to accommodate major risk intervention actions, such as the shutting down of industrial equipment or the removal of vehicles from garages. 11% of all examined target sites have a 50% chance of receiving an EEW alert that allows time for people to “drop, cover and hold on”, shut off gas supplies, or evacuate ground floors in buildings. Even in a “worst case scenario”, more than 5% of target sites have enough warning time for the switching on of semi-active control systems in structures⁴⁰, which could significantly reduce structural vulnerability and resulting damage/loss. We found that the longest overall lead times occur at sites in Iceland, Greece, and Turkey. Areas associated with the shortest overall lead times, and therefore where the feasibility of EEW could be particularly improved through increased seismic station density, are northern Iraq, north-western Georgia, and southern Russia.

The lead times were computed using a sophisticated travel-time model accounting for wave-motion physics. Our subsequent benchmarking study compared the summary maps with lead times computed using a notably more simplistic travel-time method, which does not accurately consider wave propagation; similar versions of this method are frequently used in the literature for assessing EEW feasibility. We found that positive lead times calculated using the simplistic travel-time method tend to be over-estimated, which may result in unconservative and therefore sub-optimal decision-making by a stakeholder. Additional benchmarking studies that used higher resolution maps of Italian-specific lead times confirmed the adequate accuracy of the European-wide maps.

We further contextualised the significance of the lead times by combining them with spatial distributions of two risk proxies often used in earthquake engineering (i.e., population and seismic intensity). We found that almost all (i.e., approximately 98%) of the affected ambient population are exposed to average seismic intensities from nearby seismic sources that at least result in some falling objects. More than 50% of these people have greater than 10 seconds of warning time in a “best case

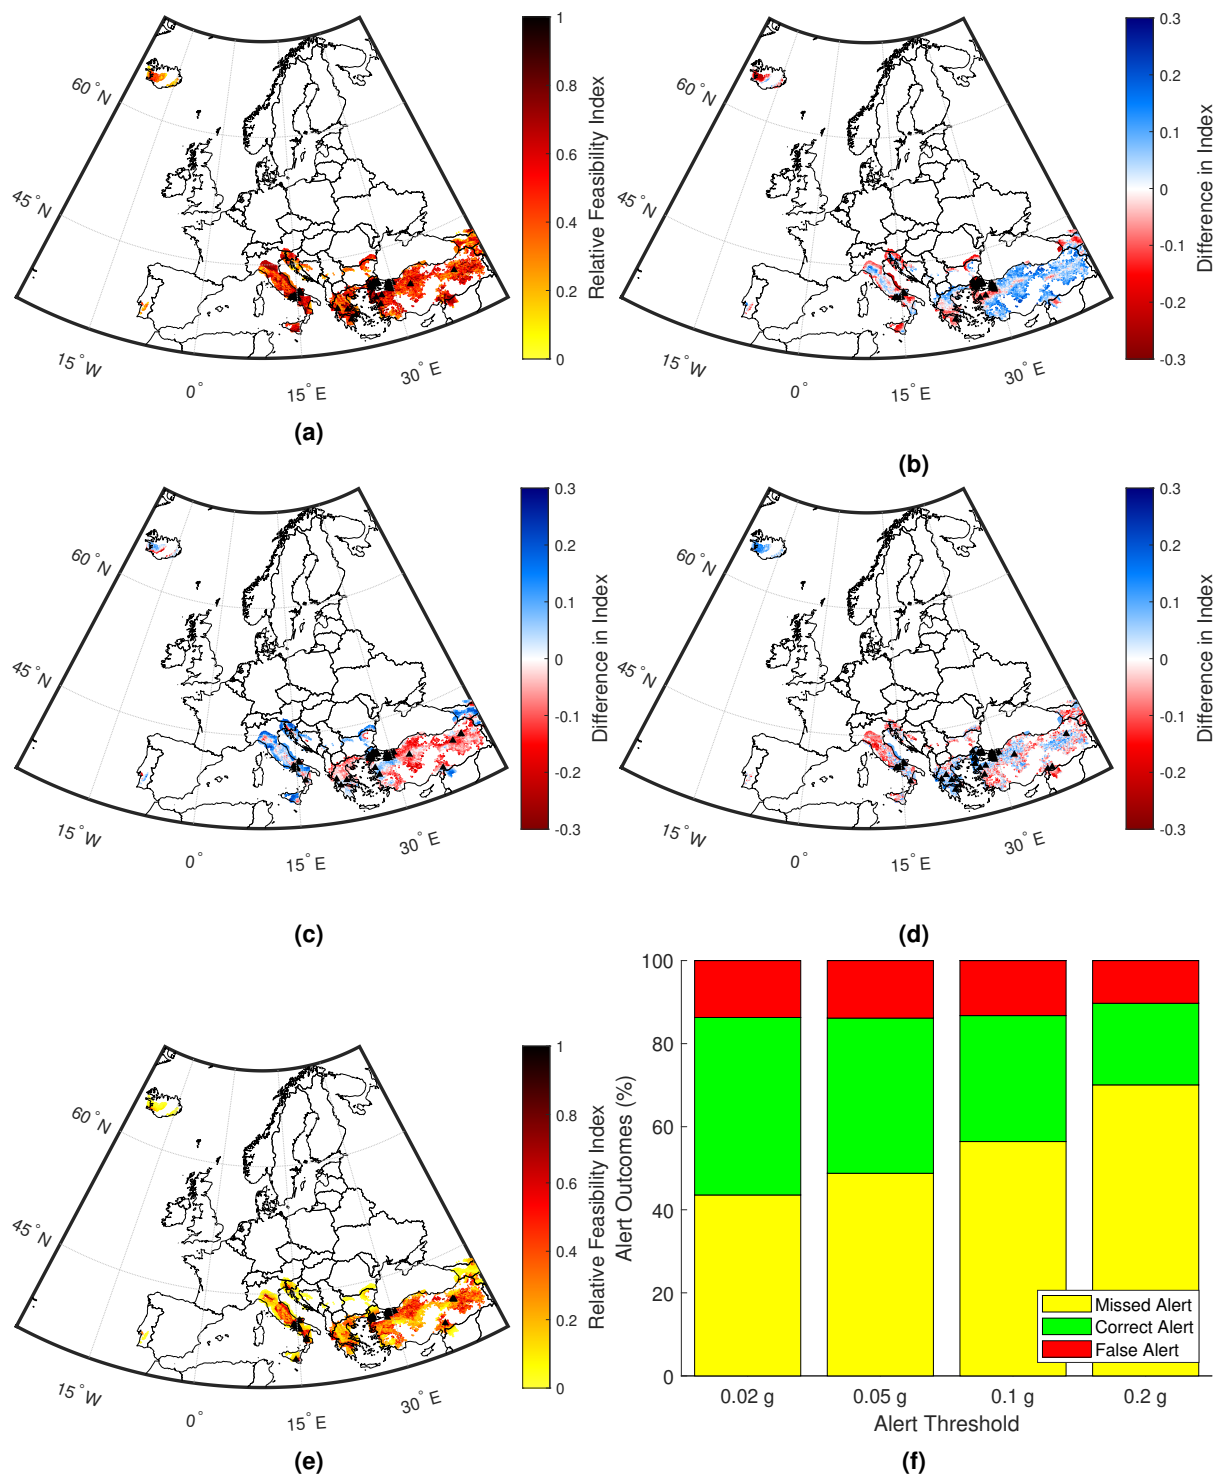

Figure 8

scenario”, which enables them to carry out the major risk intervention actions mentioned in the previous paragraph. A significant proportion ($> 55\%$) have positive warning times from events at 50% of relevant sources, while approximately 8% have some warning time in a “worst case scenario”.

Finally, we translated the aforementioned features (i.e., (1) lead time; (2) average seismic intensity from nearby sources; and (3) ambient population affected) into a novel indicator for measuring relative EEW feasibility at a given target site that also accounts for stakeholder-specific preferences. A corresponding feasibility map was developed for the case in which the features were equally weighted, as well as cases where each feature was weighted three times more than the other two. While there was some variation in the results obtained for different weighting strategies, all maps indicated that Turkey, Italy, and Greece contain the target sites with the highest EEW feasibility. We additionally examined the impact of alert accuracy on the equally weighted feasibility map, and found that Turkey, Italy, and Greece still demonstrated the highest feasibility (along with Iceland). The indices of some target sites were significantly reduced (by up to almost 90%) in this case. However, this outcome is highly dependent on the assumed alert threshold (i.e., 0.05 g)²³. Using an alternative threshold of 0.02 g, for example, would have increased the accuracy of the worst-performing source-site combination by more than 20 times, due to less missed alerts. Note that in reality, the optimal threshold will be application-specific, depending on structural characteristics at the target site⁴¹ as well as stakeholder preferences/tolerances towards risk⁶.

The findings of this study suggest that an expansion/enhancement of Istanbul-focused EEW efforts could be significantly beneficial for mitigating seismic risk in many regions throughout Turkey. The results are particularly notable for Italy and Greece, since neither has a currently operational EEW system. In summary, we ultimately conclude that this work provides strong evidence to suggest that EEW could be an effective tool for supporting earthquake-related disaster risk reduction across a significant proportion of Europe. A new three-year Horizon 2020 European research project called TURNkey (*Towards more Earthquake-resilient Urban Societies through a Multi-sensor-based Information System enabling Earthquake Forecasting, Early Warning and Rapid Response actions*; see **Acknowledgements** section) aims to address this issue by developing a holistic earthquake information system that incorporates state-of-the-art seismic risk mitigation tools for both operational earthquake forecasting and EEW in real- and near-real time, with selected testbeds in Italy and Greece (as well as Iceland) to be the focus of more detailed analyses for EEW and the target of end-user-orientated applications of the system.

It is important to note that there are some limitations/simplifying assumptions associated with this work. Firstly, it is assumed that the seismic stations currently installed across the Euro-Mediterranean area (both permanent and temporary) are capable of being used for early warning purposes (i.e., they have adequate data acquisition/transmission systems, real-time communication capability, robust dissemination methods, power supply systems, etc.^{14,24}), which may be an over-simplification¹. We did not explicitly consider the performance of existing EEW algorithms in the lead-time calculations. Instead, we simply assumed that four seconds was sufficient to capture both data telemetry delays and the length of time required by the algorithms to estimate relevant source parameters (see **Methods** section); a slightly longer time (\sim five seconds) may be required for certain algorithms and transmission features^{42,43}. Our detailed EEW feasibility analysis only accounted for crustal seismic sources, thereby yielding conservative lead times for target sites that would additionally be affected by the deeper seismicity of subduction zones in the Central and Eastern Mediterranean Sea. It therefore also neglected the seismicity of the Vrancea region in Romania⁴⁴, which has significant associated hazard⁴⁵; examination of this region is not crucial in the context of our study however, given that it already has an operational EEW system^{12,46}. To maintain a consistent approach for the entire examined region, the considered seismicity scenarios were defined using an area source model (see **Methods** section), which assumes a uniform occurrence of earthquakes as point sources; thus, the resulting calculations of hazard near faults (large seismogenic sources) may not be completely realistic⁴⁷. Our approach to quantifying alert accuracy only considered the variability of a ground motion model²³. Precisely characterising warning accuracy would involve more detailed analysis with the specific algorithms of operational EEW platforms, including the quantification and propagation of uncertainties at each step of the calculations. This type of examination was carried out for select testbed sites across Europe in a previous study by the same authors⁴⁸. It is outside the scope of this paper, given the continent-wide extent of the study. Finally, we did not consider the economic value of EEW, i.e., the costs required to build and maintain EEW systems compared to the monetary savings they provide through avoided damage⁴⁹. Despite these constraints, this study nevertheless represents an innovative attempt to comprehensively quantify EEW feasibility on a continental scale and to identify priority regions for more detailed EEW feasibility analyses/investment in EEW implementation.

Methods

Data Descriptions

Seismic Stations

Seismic station locations are obtained using the IRIS Google map (GMAP) station mapping service (<http://ds.iris.edu/gmap/>). We consider all stations (both temporary and permanent arrays) between -26° and 45° longitude, and 34° and 72° latitude that were in operation until at least the start of 2020.

Seismic Sources

We use the area source model of the 2013 European Seismic Hazard Model, which accounts for crustal seismicity with depth ≤ 40 km^{50,51}. To define seismic sources, we discretise the model into $0.1^\circ \times 0.1^\circ$ cells. We specifically make use of the depth, maximum magnitude, style-of-faulting, and Gutenberg-Richter a,b parameters from the model. Each source is assumed to be characterised by all parameter values associated with the corresponding area source zone. We use the values associated with the highest weight in the logic tree, where applicable, and average depth values for stable continental regions. The moment magnitude of the event with a recurrence interval of 500 years for a given source (m) satisfies the following equation:

$$\lambda_m - \lambda_{m_{max}} = 0.002 \quad (1)$$

where λ_m is the annual rate of earthquakes with magnitude greater than m , according to the Gutenberg-Richter magnitude-frequency relationship⁵², and m_{max} is the modal maximum magnitude for the given source. We focus on the 37,869 sources for which $m \geq 6.5$. The catalog generated to quantify alert accuracy consists of 1,000 earthquakes per source that are Gutenberg-Richter distributed and have uniform annual rates of occurrence (from equation 1) between 0 and 1. Predictions of PGA and peak ground velocity (PGV) associated with all events are computed/sampled using the epicentral distance version of the Akkar et al. ground motion model⁵³. The site amplification input to this model is the shear wave velocity in the uppermost 30 m, which is estimated at each target site from a topographic slope map⁵⁴.

For the benchmarking study of Italy, the area source zones are instead discretised into $0.05^\circ \times 0.05^\circ$ cells, which is equivalent to the resolution used in the country's official seismic hazard map⁵⁵. Assignments/calculations of seismic parameter values and ground shaking intensity predictions are as described for the European-wide seismic sources. This results in a total of 4804 sources that satisfy the M_w 6.5 threshold for the events with a recurrence interval of 500 years and result in a PGA greater than 0.05 g for at least one target site of interest.

Target Sites

Target sites are equivalent to all land-based seismic sources (i.e. those without a water layer at or above zero-elevation in the corresponding 1-D velocity profile; see **Travel Times** section), located within the same coordinate boundaries as the seismic stations. Target sites for the Italian benchmarking study are defined as all land-based seismic sources that are categorised under 'Italy' in the 'Countries WGS84' shapefile, retrieved from the ArcGIS Hub (<https://hub.arcgis.com/search>).

Seismic Station Density

Interstation distance for a given seismic station is the average distance to the closest three stations.

Lead-time Modelling

Travel Times

We use the travel time algorithm of the open-source NonLinLoc software package (<http://alomal.free.fr/nlloc/>)⁵⁶. This method calculates first arrival travel times for the nodes of a spatial grid using the Eikonal finite-difference scheme of Podvin and Lecomte³¹, which is an approximation of Huygen's principle⁵⁷. We use a grid spacing of 10 km (5 km for the Italy benchmarking case study) in all directions, and incorporate a normally distributed zero-mean timing error with 0.2 variance. Both source-to-site and source-to-station travel times are calculated using 1-D velocity profiles from the CRUST 1.0 velocity model⁵⁸, at the location of the target site. Note that travel times are computed to zero-elevation at the target site.

Travel Times (Simplified Model)

Simplified source-to-site and source-to-station travel times are computed as follows:

$$TT_{x,y} = \frac{d_{hypo_{x,y}}}{v_{avg}} \quad (2)$$

where x is the source, y is the target site or station of interest, $d_{hypo_{x,y}}$ is the hypocentral distance between x and y , and v_{avg} is the average P- or S-wave velocity across the CRUST 1.0 velocity model profile, at the location of the target site. Travel times are computed to zero-elevation at the target site.

Lead-Time Calculation

The lead-time (in seconds) for target site j due to an event at a given seismic source a is calculated as follows:

$$LT_j = TT_{a,j}^s - TT_{a,st_3}^p - 4 \quad (3)$$

where $TT_{a,j}^s$ is the S-wave arrival time at j , and TT_{a,st_3}^p is the P-wave arrival time at the third closest station to the source. We account for the triggering of three stations, as it is the minimum required for many popular regional EEW algorithms to report reliable source parameter estimates^{59–61}. A four-second interval is assumed to capture both data telemetry delays and the P-wave window required by an EEW algorithm to compute location/magnitude estimates, in line with previous studies¹⁵.

Risk Modelling

Seismic intensities are calculated from the bilinear equations for EMS-98 macroseismic intensity developed by Masi et al.⁶², using median PGV predictions (see **Seismic Sources** section). Population data are obtained from the 2018 LandScan database⁶³, which contains global ambient population distributions at a $30'' \times 30''$ spatial resolution. Each target site is assigned the aggregated population across all LandScan grid points closest to it.

EEW Feasibility Modelling

The relative feasibility index measure for target site j (RF_j) considers its associated values of median lead-time (L), average seismic intensity (I), and ambient population (P):

$$RF_j = F_L(L_j) \times w_L + F_I(i_j) \times w_I + F_P(p_j) \times w_P \quad (4)$$

where $F_X(x_k)$ is the empirical cumulative distribution function of X (across all examined target sites with positive median lead time) evaluated at k , and w_X is the stakeholder-assigned weight for X (note that $w_P + w_I + w_L = 1$).

RF_j is modified to account for alert accuracy, as follows:

$$RF_{j,alert} = RF_j \times F_{CA}(ca_j) \quad (5)$$

where ca_j is the proportion of correct alerts at site j , calculated according to:

$$ca_j = \frac{n_{ca,j}}{n_j} \quad (6)$$

n_j is the total number of catalog earthquakes examined for j (see **Seismic Sources** section), which is all events from sources considered in the lead-time calculation that yield a predicted median PGA at the site of at least 0.001 g and result in either a false alert, a missed alert, or a correct alert ($n_{CA,j}$) - we ignore cases where the system correctly issues no alert, in line with Minson et al²³. A false alert occurs if the predicted median PGA exceeds the threshold and the actual (randomly simulated) PGA does not, while a missed alert occurs in the opposite case. All other considered combinations of predicted median and actual ground shaking produce a correct alert.

Data Availability

We obtained seismic station locations from the IRIS Google map (GMAP) station mapping service (<http://ds.iris.edu/gmap/>). Seismic source data and general target site locations were retrieved from the 2013 European Seismic Hazard Model^{50,51}. We determined target sites for the Italian benchmarking study using the 'Countries WGS84' shapefile in the ArcGIS Hub (<https://hub.arcgis.com/search>). We obtained estimates of shear wave velocity in the uppermost 30 m from the database of Wald and Allen⁵⁴. Velocity profiles were acquired from the CRUST 1.0 dataset⁵⁸. Population data were obtained from the 2018 Landscan database⁶³.

Code Availability

All code used in this research is available from the authors upon request.

Acknowledgements

We thank Dr. Alireza Azarbakht and Dr. John Douglas (University of Strathclyde, UK) for helpful feedback on parts of this study. This paper is supported by the European Union's Horizon 2020 research and innovation programme under grant agreement No 821046, project TURNkey (Towards more Earthquake-resilient Urban Societies through a Multi-sensor-based Information System enabling Earthquake Forecasting, Early Warning and Rapid Response actions; <https://earthquake-turnkey.eu/>).

Author contributions statement

GC and CG conceived and designed the research. GC drafted the written content of the manuscript, which all authors reviewed. GC performed the calculations. GC and CG developed the figures. EZ provided EEW and seismic hazard expertise.

Materials and Correspondence

Correspondence to Gemma Cremen (g.cremen@ucl.ac.uk).

Competing interests

The authors declare no competing interests.

Figure Legends

1. **Figure 1.** Examining seismic station coverage across Europe. (a) Map of European seismic stations considered and (b) distribution of interstation distances.
2. **Figure 2.** Input data for lead-time mapping calculations. (a) Seismic sources (colour coded in accordance with corresponding modal maximum magnitude values from the seismic hazard model) and (b) target sites examined for lead-time calculations.
3. **Figure 3.** Distributions of lead times for target sites in three major European capital cities. (a) Site in Rome, (b) site in Istanbul, and (c) site in Athens. Note that the red dashed lines indicate the corresponding median lead times and the black solid lines denote the positive lead-time threshold.
4. **Figure 4.** Lead-time mapping across all examined target sites. (a) Minimum lead times (b) median lead times, and (c) maximum lead times.
5. **Figure 5.** Differences obtained in lead-time maps, using the simplified travel time model. (a) Differences in minimum lead times, (b) differences in median lead times, and (c) differences in maximum lead times. Red colours indicate larger - and blue colours indicate smaller - lead times for the simplified case.
6. **Figure 6.** High-resolution lead-time maps of Italy. (a) Minimum lead times, (b) median lead times, and (c) maximum lead-times, to be compared with the corresponding times mapped in Figure 4.
7. **Figure 7.** Examining the risk-mitigation potential of calculated lead times. Average EMS-98 macroseismic intensities experienced by the affected ambient population during events with a recurrence interval of 500 years that resulted in at least 0.05 g PGA at the associated target site, categorised by the corresponding times of the maps presented in Figure 4. Note that seismic intensities V, VI, and VII denote “strong”, “slightly damaging”, and “damaging” events, respectively.
8. **Figure 8.** Relative Feasibility Index mapping across examined target sites. Indices for (a) the case in which lead time, intensity, and population are equally weighted by a stakeholder, as well as differences for cases in which (b) lead time, (c) seismic intensity, and (d) population are respectively weighted three times more than both other variables. Also shown are (e) equally weighted indices scaled by the relative number of correctly issued alerts (for 0.05 g alert threshold) and (f) the proportion of different alert outcomes across all of the thresholds examined in²³. Note that for (b)-(d), red colours indicate an increase in the index relative to (a) and blue colours indicate a relative decrease. Black triangles indicate target sites with one of the fifty largest indices for each case.

Table

Lead Time Range (s)	Possible Actions
0-5	<ul style="list-style-type: none"> • Stopping traffic (i.e., turning lights red) • Switching on semi-active control systems for structures
5-10	<ul style="list-style-type: none"> • Performing DCHO • Stopping elevators at the nearest floor and opening doors • Shutting off gas supplies • Shutting down computers and related equipment • Evacuating the ground floor of buildings
> 10	<ul style="list-style-type: none"> • Shutting down industrial equipment • Controlling production lines • Directing traffic away from underpasses • Stopping surgical procedures • Removing vehicles from garages

Table 1. Possible risk-mitigation actions that can be taken by various stakeholders for different lengths of EEW lead time (adapted from previous work^{3,19,34,64,65}).
