Abstract

Subseasonal timescales (~ 2 weeks - 2 months) are known for their lack of predictability, however, specific Earth system states known to have a strong influence on these timescales can be harnessed to improve prediction skill (known as “forecasts of opportunity”). As the climate continues warming, it is hypothesized these states may change and consequently, their importance for subseasonal prediction may also be impacted. Here, we examine changes to midlatitude subseasonal prediction skill provided by the tropics under anthropogenic warming using artificial neural networks to quantify skill. The network is tasked to predict the sign of the 500hPa geopotential height for historical and future time periods in the CESM2-LE across the Northern Hemisphere at a 3 week lead using tropical precipitation. We show prediction skill changes substantially in key midlatitude regions and these changes appear linked to changes in seasonal variability with the largest differences in accuracy occurring during forecasts of opportunity.

Plain Language Summary

Predictions on 2 week to 2 month (subseasonal) timescales are important for the public and private sectors due to the increased preparation time provided to save lives and property. In the current climate, signals initiated in the tropics can overpower noise in the midlatitudes and ultimately lead to enhanced midlatitude subseasonal prediction skill. However, it has been hypothesized that increasing global temperatures due to climate change may impact these signals and their sources in the future. Therefore, it is important to understand how subseasonal predictability provided by the tropics will be affected. Here, we utilize a type of machine learning known as a neural network to investigate this question. We find that subseasonal prediction skill provided by the tropics changes throughout the Northern Hemisphere in a warmer climate and these changes appear mainly linked to changes in seasonal variability. In addition, we see that the largest differences in accuracy occur during opportunities for enhanced subseasonal prediction skill.

1 Introduction

Accurate predictions on subseasonal timescales (2 weeks - 2 months) are important for many public and private sectors such as water management and agriculture (White et al., 2021). This is because prediction on these timescales provides pivotal lead times for saving lives and property in these sectors (White et al., 2021). The tropics is of particular importance for this timescale because of intraseasonal phenomena like the Madden-Julian Oscillation (MJO; Madden & Julian, 1971, 1972). Quasi-stationary Rossby waves generated by upper level divergence associated with MJO convection (Hoskins & Ambrizzi, 1993) can modulate midlatitude circulation in the following weeks (e.g. Hoskins & Karoly, 1981; Sardeshmukh & Hoskins, 1988; Henderson et al., 2016; Baggett et al., 2017; Zheng et al., 2018) and these tropical-extratropical teleconnections are known to lead to enhanced midlatitude prediction skill on subseasonal lead times (Tseng et al., 2018). Phenomena like the El Niño Southern Oscillation (ENSO), an interannual oceanic mode in the tropical Pacific Ocean (Trenberth, 1997), can also impact subseasonal prediction. It can do so through modulation of the MJO (e.g. Hendon et al., 1999; Kessler, 2001; Pohl & Matthews, 2007) or modulation of the large-scale background state (e.g. Namias, 1986; Moon et al., 2011; Takahashi & Shirooka, 2014), and both can ultimately impact teleconnection propagation (e.g. Stan et al., 2017; Henderson & Maloney, 2018; Tseng et al., 2020; Arcodia et al., 2020) and subseasonal prediction skill (e.g. Johnson et al., 2014; L. Wang & Robertson, 2019). Therefore, when phenomena like the MJO and ENSO are present, they can provide a predictable signal above climate noise and be used to enhance subseasonal prediction skill, known as forecasts of opportunity (Mariotti et al., 2020).

63 The current understanding of the importance of the tropics on midlatitude sub-
64 seasonal predictability is rooted in our knowledge of the historical climate. However, with
65 the climate continuously warming, it is unclear how transferable this knowledge will be
66 to a future, warmer climate. Therefore, research on subseasonal timescales has exam-
67 ined how the MJO (Maloney et al., 2018) and ENSO (Cai et al., 2021) will change in
68 the future as well as the subsequent changes to their teleconnections (e.g. Samarasinghe
69 et al., 2021; W. Zhou et al., 2020; Cui & Li, 2021; Meehl et al., 2007; Z.-Q. Zhou et al.,
70 2014; Drouard & Cassou, 2019; Fereday et al., 2020; Beverley et al., 2021). It stands to
71 reason that these changes will likely impact subseasonal predictability across the North-
72 ern Hemisphere, but little work has been done in this area (an example being Sheshadri
73 et al., 2021). Here, we utilize the Community Earth System Model Version 2 - Large En-
74 semble (CESM2-LE; Rodgers et al., 2021) and simple artificial neural networks to iden-
75 tify changes in subseasonal predictability provided by the tropics under future warm-
76 ing.

77 In recent years, neural networks have been successfully applied to weather and cli-
78 mate prediction (e.g. Chapman et al., 2021; Ham et al., 2019; Gordon et al., 2021; Rasp
79 & Thuerey, 2021; Weyn et al., 2021; Martin et al., 2022; Labe & Barnes, 2022) due to
80 their ability to extract nonlinear relationships from large amounts of data. This makes
81 them advantageous for learning nonlinear relationships in the climate system. In addi-
82 tion, recent advances in explainability techniques and their application to climate sci-
83 ences demonstrate that neural networks can identify physical relationships in the Earth
84 system (e.g. McGovern et al., 2019; Toms et al., 2020; Mayer & Barnes, 2021; Daven-
85 port & Diffenbaugh, 2021). For example, Mayer and Barnes (2021) demonstrate that neu-
86 ral networks can be used to identify subseasonal forecasts of opportunity through the
87 neural network’s confidence in a given prediction. They further show that the network
88 identifies physically meaningful sources of subseasonal predictability for the North At-
89 lantic.

90 Here we use artificial neural networks to quantify how subseasonal prediction skill
91 provided by the tropics may change under future climate warming. Given the importance
92 of forecasts of opportunity for subseasonal prediction in the current climate, we exam-
93 ine both total changes to overall prediction skill as well as changes to skill during fore-
94 casts of opportunity, in particular. The artificial neural networks identify subseasonal
95 prediction skill changes across the Northern Hemisphere in the CESM2-LE. In partic-
96 ular, there is an increase in prediction skill over the North Atlantic and western North
97 America as well as a decrease over the North Pacific. In addition, this approach shows
98 that the greatest changes in skill occur during forecasts of opportunity and that these
99 changes appear linked to changes in seasonal variability in the CESM2-LE.

100 2 Data and Methods

101 2.1 Data

102 Here, we examine midlatitude subseasonal prediction skill changes using the first
103 10 members from the coupled Community Earth System Model Version 2 - Large En-
104 semble (CESM2-LE; Rodgers et al., 2021). CESM2 has both a well represented MJO (Ahn
105 et al., 2020) and MJO teleconnections (J. Wang et al., 2022) and thus, is ideal for this
106 analysis. We note that the results presented are specifically for the CESM2-LE, and as
107 with all model-based results, are dependent on specific model biases (e.g. SST biases;
108 Danabasoglu et al., 2020). We use the years 1970-2015 as our ‘historical period’ to rep-
109 resent a climate similar to today and compare it to the latter half of the century (2055-
110 2100; ‘future period’) under the SSP3-7.0 climate change scenario. We find that 10 mem-
111 bers are sufficient for this analysis as the network skill plateaus when at least 5 ense-
112 mble members are used for training, depending on location and time period (Figure S1;
113 Text S1). While additional ensemble members could be used, we believe our conclusions

114 would remain unaffected, as the sign of the change in prediction skill of the 20% most
 115 confident predictions remains consistent regardless of the number of members examined
 116 here.

117 The CESM2-LE members #1-10 are split into training (members #1-8), valida-
 118 tion (member #9) and testing data (member #10). To simultaneously detrend and re-
 119 move the seasonal cycle for each grid point, the 3rd order polynomial fit of the training
 120 and validation members' ensemble mean is subtracted from every ensemble member in-
 121 dividually for each day of the year. We find the conclusions are insensitive to the spec-
 122 ific members assigned to training, validation and testing (Figure S2).

123 We utilize the CESM2-LE tropical precipitation (28.5°S-28.5°N) and geopotential
 124 height at 500 hPa (z500; 31.25°N-88.75°N) during the extended boreal winter (November-
 125 March) since this is when MJO teleconnections tend to be strongest (Madden 1986). Trop-
 126 ical precipitation anomalies are computed for each member and grid point by standard-
 127 izing with the training data mean and standard deviation. For computational purposes,
 128 the z500 field is partitioned into non-overlapping 5° x 5° boxes, where the average of these
 129 values is assigned to the center grid point latitude and longitude. This decreases the z500
 130 resolution from 2.5° x 2.5° to 7.5° x 7.5°, however, given the large scale structure of z500,
 131 we do not expect the resolution reduction to impact the conclusions. The sign of the z500
 132 anomalies are defined by subtracting the training data median from the training, val-
 133 idation and testing data and converting the anomalies into 0s and 1s depending on the
 134 sign (negative and positive, respectively).

135 Sea surface temperatures (SST) from the first 10 members of the CESM2-LE are
 136 also used to calculate the Niño 3.4 index for each member, following the *NCAR Climate*
 137 *Data Guide* (2020). The trend and seasonal cycle is removed simultaneously as afore-
 138 mentioned, and a 5 month running mean is applied prior to standardizing the SSTs with
 139 each member's mean and standard deviation. An El Niño/La Niña event is therefore de-
 140 fined as a standardized Niño 3.4 index value of greater/less than +/- 1 σ . We use this
 141 index to examine any possible role that ENSO may play in the identified changes to sub-
 142 seasonal predictability.

143 **2.2 Neural Network Architecture and Application**

144 The neural network ingests daily tropical precipitation anomalies and makes a pre-
 145 diction of the sign of z500 at a given grid point at a lead of 21 days (Week 3; Figure 1a).
 146 Prediction of the sign of z500 at each grid point allows the network freedom to learn im-
 147 portant patterns and relationships between tropical precipitation and z500. The num-
 148 ber of input nodes is equal to the number of precipitation grid points (N=3456). The
 149 first and second layer of the network consist of 128 and 8 nodes, respectively. A softmax
 150 activation function is applied to the output layer of 2 nodes which transforms the net-
 151 work output into values which sum to one. These transformed values represent a net-
 152 work estimation of likelihood, which we refer to as 'model confidence', where the pre-
 153 dicted category is defined as a value greater than 0.5. As shown in Mayer and Barnes
 154 (2021), when prediction skill increases with model confidence, higher model confidence
 155 can be used to identify subseasonal forecasts of opportunity.

156 We use this network architecture because it has some of the highest validation skill
 157 for both the historical and the future time periods in the North Atlantic and also per-
 158 forms well in the North Pacific (Figure S3-S4). We note that slight variations of the hy-
 159 perparameters (i.e. network depth, nodes per layer, learning rate, ridge regression pa-
 160 rameter) show similar skill. While one could optimize the architecture and hyperparam-
 161 eters for every gridpoint individually, we have not done this due to the considerable com-
 162 putational resources necessary and find it unlikely to lead to substantially different con-
 163 clusions. For additional information on the network architecture and hyperparameters
 164 see Text S2.

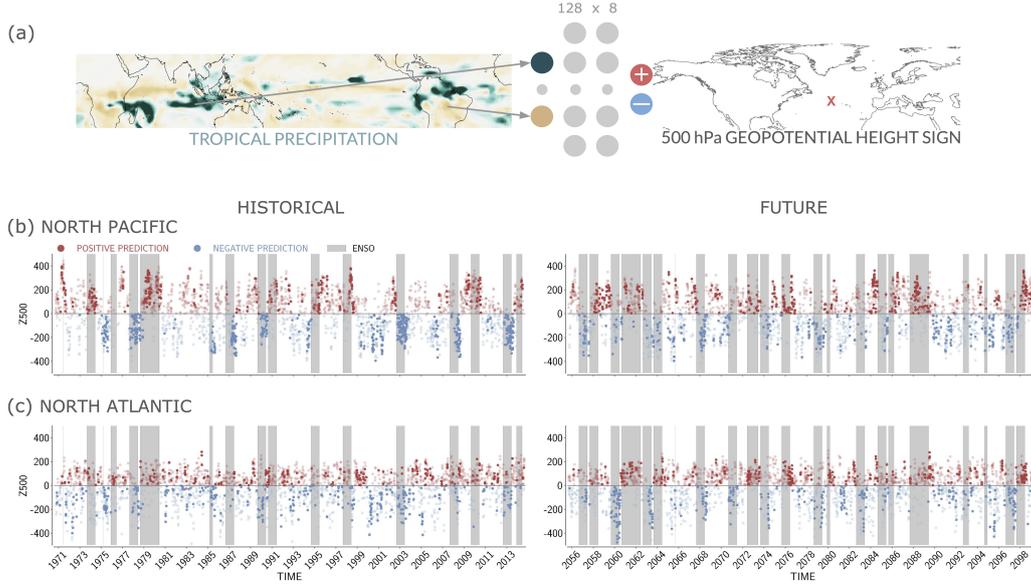

Figure 1. (a) The artificial neural network input (tropical precipitation), architecture (first hidden layer: 128 nodes, second hidden layer: 8 nodes) and output (sign of z500hPa at a location ‘x’). (b,c) Timeseries of the *correct* sign predictions of z500 in ensemble member #10 for the historical (left column) and future (right column) for (b) the North Pacific and (c) the North Atlantic. Red (blue) dots indicate positive (negative) predictions. Darker dots denote the 20% most confident predictions, and the grey shading indicates when the standardized Niño 3.4 index exceeds $\pm 1\sigma$.

165 Example correct network predictions for the testing ensemble member #10 are shown
 166 in Figure 1(b-c) for the historical (left column) and the future (right column) periods
 167 in (b) the North Pacific and (c) the North Atlantic. The color denotes the sign of the
 168 prediction and the darker colors denote the (20% most) confident predictions. The ver-
 169 tical grey shading indicates periods of ENSO events. Figure 1(b-c) demonstrates that
 170 the networks can accurately and confidently predict both sign anomalies. In addition,
 171 it shows a possible relationship between confident subseasonal predictions and ENSO events,
 172 but the amount which confident predictions coincide with ENSO events depends on lo-
 173 cation and time period. This relationship will be addressed further in section 3.2.

174 3 Results

175 3.1 Changes in Subseasonal Prediction Skill

176 To examine how subseasonal prediction skill provided by tropical-extratropical tele-
 177 connections changes in a warmer climate, 100 networks are trained for the North Pacific
 178 (41.25°N, 205°E) and the North Atlantic (41.25°N, 325°E) for both the historical and
 179 future periods. These two locations are chosen because they encompass regions known
 180 to be significantly impacted by the MJO (e.g. Mori & Watanabe, 2008; Cassou, 2008;
 181 Lin et al., 2009) and ENSO (e.g. Wallace & Gutzler, 1981; Zhang et al., 1996) telecon-
 182 nections, which subsequently have North American and European impacts. The 100 net-
 183 works are created by varying their random seed to test the sensitivity of the network to
 184 the random initialized weights.

185 Accuracies binned by various model confidence thresholds are shown in Figure 2.
 186 Accuracy increases with model confidence (moving from left to right), suggesting the net-
 187 work is identifying forecasts of opportunity for these regions. In addition, we find that
 188 all networks at almost every confidence level perform better than random chance (Fig-
 189 ure 2, Text S3). The North Pacific (Figure 2a) has higher accuracy compared to the North
 190 Atlantic (Figure 2c), likely due to the strong influence of tropical phenomena like the
 191 MJO and ENSO in modulating the circulation in the North Pacific (e.g. Wallace & Gut-
 192 zler, 1981; Zhang et al., 1996; Mori & Watanabe, 2008; Roundy et al., 2010; Riddle et
 193 al., 2013). In the future, subseasonal prediction skill increases in the North Atlantic (Fig-
 194 ure 2c) and decreases in the North Pacific (Figure 2a) in the CESM2-LE, and this is most
 195 evident at higher confidence values. If one examines the accuracy for all (100% most con-
 196 fident) predictions, the North Atlantic and North Pacific accuracies exhibit almost no
 197 difference between the two time periods. It is when we focus on the higher confidence
 198 predictions that a clear signal emerges. In other words, the changes in subseasonal pre-
 199 diction skill are most evident during forecasts of opportunity in these regions.

200 Histograms of the accuracies at the 20% most confident threshold (Figure 2 b,d)
 201 further show that the future period has substantially shifted away from the historical
 202 period in both regions. The majority of the future North Atlantic accuracies exceed the
 203 95th percentile of the historical accuracies, and all of the future North Pacific accura-
 204 cies lie below the 5th percentile of the historical accuracies.

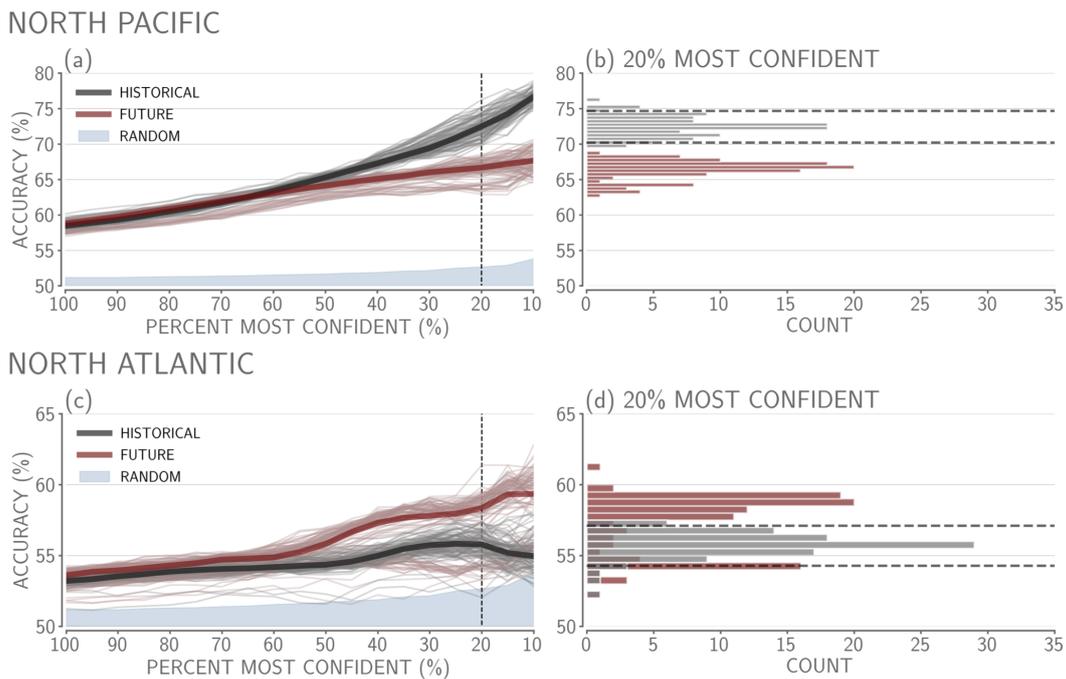

Figure 2. (a,c) Accuracy versus confidence for 100 trained networks in the North Pacific and the North Atlantic from testing member #10. Testing samples are subset so that random chance for all predictions is 50%. Thick grey and red lines denote the median accuracy across the 100 networks at each confidence threshold. Vertical black dashed lines indicate the 20% most confident predictions. (b,d) Histograms of the 100 accuracies at the 20% most confident threshold, using a bin size of 0.5%. Horizontal grey dashed lines indicate the 5th and 95th percentile bounds of the historical accuracies at the 20% most confident level.

205 To explore whether the results in Figure 2 hold for other regions, we train 10 neu-
 206 ral networks for each grid point and time period across the Northern Hemisphere. We
 207 train 10 networks instead of 100 for computational efficiency. To test whether these changes
 208 in skill in the North Atlantic and North Pacific could be seen with only 10 networks, we
 209 conducted a bootstrapping analysis (Text S4; Figure S5) following the method used to
 210 create Figure 3, and find that 10 networks are sufficient for identifying these changes.
 211 Figure 3 shows the resulting mean testing accuracy of the top three of the 10 networks
 212 for each location. The top three networks are defined as the networks with the three high-
 213 est 20% most confident validation accuracies. We use the top three networks so that the
 214 mean accuracies for each region are not as influenced by models that learn very little or
 215 not at all.

216 For all predictions (Figure 3a-b) and 20% most confident predictions (“confident
 217 predictions” from here on; Figure 3d-e), the locations of highest skill are in regions as-
 218 sociated with the Pacific/North America pattern (PNA; Wallace & Gutzler, 1981). The
 219 higher accuracies over PNA regions suggests the network is most likely identifying fore-
 220 casts of opportunity associated with teleconnections from the MJO and/or ENSO (e.g.
 221 Wallace & Gutzler, 1981; Zhang et al., 1996; Mori & Watanabe, 2008; Roundy et al., 2010;
 222 Riddle et al., 2013). We also find that the spatial coherence in accuracies across networks
 223 corresponds to the networks correctly predicting many of the same days for neighbor-
 224 ing grid points (not shown). In the future period (Figure 3b,e), there is an additional
 225 region of higher accuracies spread across Asia and the North Atlantic. Overall, the con-
 226 fident predictions have higher accuracies than all predictions, indicating that higher model
 227 confidence predictions exhibit greater skill.

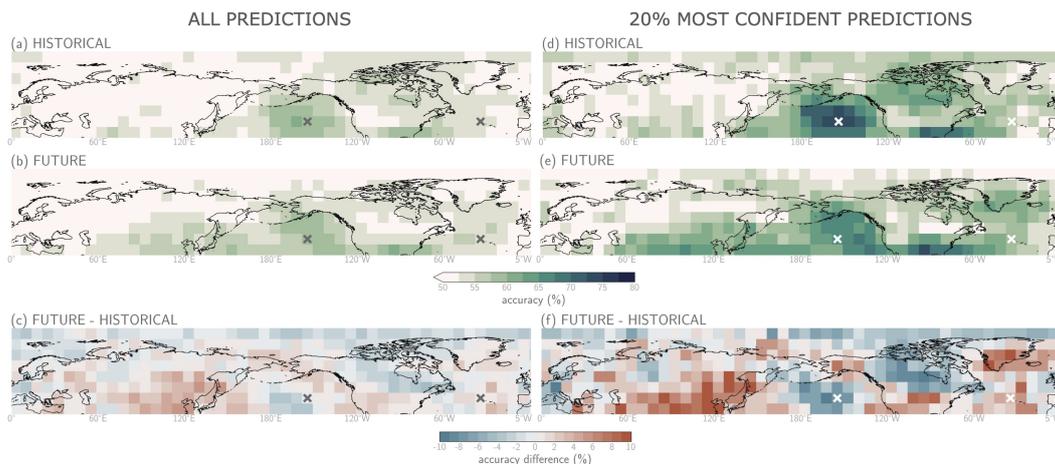

Figure 3. (a,b,d,e) Mean testing accuracy of the best 3 models for (a,b) all and (b,e) the 20% most confident predictions. (c,f) Difference in accuracy between the future and the historical time periods for (c) all and (f) the 20% most confident predictions, where red (blue) indicates an increase (decrease) in accuracy in the future. The grey and white ‘x’ indicate the North Pacific and North Atlantic regions (from left to right) used in Figures 1,2.

228 In the future, spatially coherent increases in skill are seen across Asia, along the
 229 west coast of North America, across the southern United States and throughout the North
 230 Atlantic (Figure 3c,f) while decreases are seen over the North Pacific, Canada and west-
 231 ern Europe. While the change in skill over East Asia is substantial, it appears that the
 232 overall skill in East Asia for both time periods does not harness any subseasonal vari-
 233 ability, but rather comes about exclusively from seasonal variability or longer timescales

(Figure S8-S9). As a result, these changes in skill are not addressed further here. The difference plots for both all and the confident predictions (Figure 3c,f) have similar spatial patterns of changes in accuracy, however, the confident predictions show the largest changes in skill. Specifically, the absolute maximum change in skill for all predictions is about 5% while the absolute maximum change in skill for confident predictions is about 10%. This further demonstrates that the greatest changes to subseasonal prediction skill provided by the tropics occur during forecasts of opportunity across the Northern Hemisphere, consistent with Figure 2.

3.2 Tropical Drivers of Changing Midlatitude Skill

Seasonal variability can have a large influence on subseasonal variability and prediction skill. In the tropics, ENSO can modulate the MJO (e.g. Hendon et al., 1999; Kessler, 2001; Pohl & Matthews, 2007) and the basic state (e.g. Namias, 1986; Moon et al., 2011; Takahashi & Shirooka, 2014), and ENSO teleconnections can (de)constructively interfere with MJO teleconnections (e.g. Stan et al., 2017; Henderson & Maloney, 2018; Henderson et al., 2020; Tseng et al., 2020; Arcodia et al., 2020). Recent studies have identified possible changes to both MJO and ENSO variability (Maloney et al., 2018; Cai et al., 2021) as well as their teleconnections (e.g. Fredriksen et al., 2020; Beverley et al., 2021; W. Zhou et al., 2020; Samarasinghe et al., 2021) under future climate warming. Thus, the changes in midlatitude subseasonal prediction skill seen in Figures 2 and 3 could be a reflection of changes to subseasonal variability, seasonal variability, or through a combination of changes to both.

We find that the increase in skill along the west coast of North America and in the North Atlantic is supported by previous research on MJO and ENSO teleconnections in a warmer climate. In particular, the subseasonal skill increase along the west coast of North America (Figure 3f) appears to be associated with a north-eastward shift of higher accuracies over the North Pacific in the future (Figure 3d-e). This is consistent with research showing that PNA patterns initiated by ENSO (e.g. Meehl & Teng, 2007; Meehl et al., 2007; Müller & Roeckner, 2008; Kug et al., 2010; Z.-Q. Zhou et al., 2014; Fredriksen et al., 2020; Beverley et al., 2021) and the MJO (Wolding et al., 2017; W. Zhou et al., 2020; Jenney et al., 2021; J. Wang et al., 2022) are projected to shift eastward in a warmer climate in a variety of climate models, including CESM2 (Fredriksen et al., 2020; J. Wang et al., 2022). In the North Atlantic, increased skill is also consistent with research suggesting that the North Atlantic may become more sensitive to MJO teleconnections (Samarasinghe et al., 2021) and that the ENSO-NAO teleconnection may strengthen (Drouard & Cassou, 2019; Fereday et al., 2020) in the future. The decrease in skill over the North Pacific is also consistent with recent research using a variety of CMIP6 models that suggests the ENSO teleconnection amplitude over the North Pacific may weaken in a warmer climate (e.g. Fredriksen et al., 2020; Beverley et al., 2021).

To gain insight into the neural network's identified sources of predictability, we apply explainable AI to create heatmaps of the relevant regions of the input tropical precipitation the network uses to make confident and correct predictions (see Text S5; Bach et al., 2015; Montavon et al., 2019). In the North Pacific and North Atlantic, the network tends to focus on the tropical equatorial Pacific, typically associated with ENSO (Figure S6). In the North Pacific, the future decrease in skill is associated with a decrease in relevance of the ENSO region (Figure S6a-d). For the North Atlantic, the future increase in skill is associated with an increase in relevance of the ENSO region (Figure S6e-h). These explainability results suggest that the changes in subseasonal prediction skill may be related to changes in the importance of the ENSO region (i.e. seasonal variability), even though both subseasonal and seasonal variability are contributing to the total skill (Figure S8-S9). This changing role of ENSO in both regions is also evident in the prediction timeseries in Figure 1. In the North Atlantic (Figure 1c), the confident predictions in the historical period are scattered throughout the years, whereas in the

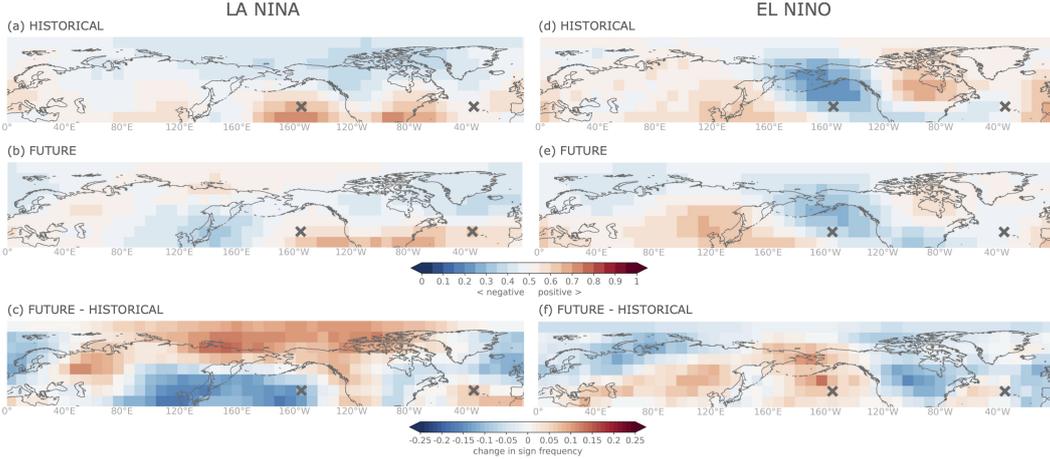

Figure 4. (a,b,d,e) Frequency of a positive sign anomaly 21 days following a standardized Niño 3.4 Index value of greater/less than $\pm 1\sigma$. Values greater (less) than 0.5 frequency indicate that positive (negative) sign anomalies are more frequent. (c,f) Difference in frequency between the future and historical time period. The left (right) column is for La Niña (El Niño). The grey ‘x’ indicate the North Pacific and North Atlantic regions (from left to right) used in Figures 1,2.

286 future period, the confident predictions correspond more frequently with ENSO events
 287 (darker dots mainly occur in the grey shading). The opposite is seen for the North Pa-
 288 cific (Figure 1b). Given the results of this analysis, we next examine if the changes in
 289 midlatitude subseasonal prediction skill are related to changes in ENSO teleconnections.

290 We analyze the relationship between ENSO teleconnections and subseasonal pre-
 291 diction skill changes across the Northern Hemisphere by calculating how often a posi-
 292 tive z500 anomaly occurs 21 days following an El Niño/La Niña event (Figure 4). This
 293 metric quantifies the consistency of specific teleconnections following ENSO events and
 294 thus, demonstrates the downstream influence of ENSO on specific regions. Therefore,
 295 any regional changes to the consistency between the two time periods implies changes
 296 to the impact of ENSO in that region. Over the North Pacific, the consistency of the z500
 297 sign following both ENSO phases decreases (Figure 4c,f), suggestive of a reduction in
 298 the influence of ENSO teleconnections. Furthermore, the large decrease in skill over Canada
 299 (Figure 3f) aligns with the decrease in El Niño teleconnection consistency in the future
 300 (Figure 4f). Over the North Atlantic, there is a slight increase in ENSO teleconnection
 301 consistency which may be related to the projected strengthening of the ENSO-NAO tele-
 302 connection in the future (Drouard & Cassou, 2019; Fereday et al., 2020). Lastly, the in-
 303 crease in skill along the west coast of North America (Figure 3f) aligns with an increase
 304 in consistency of La Niña teleconnections (Figure 4c). Thus, we hypothesize that the sub-
 305 stantial changes in subseasonal prediction skill in regions across the Northern Hemisphere
 306 are connected to changes in ENSO teleconnections in the CESM2-LE.

307 We provide further evidence of the role of seasonal variability in changes to sub-
 308 seasonal prediction skill through an additional neural network analysis in the North Pa-
 309 cific and North Atlantic. We filter out 60+ day variability from the z500 anomalies (Text
 310 S6) to remove low-frequency signals such as those from ENSO teleconnections. With this
 311 filtering, there is almost no change in skill between the historical and future period in
 312 the North Pacific (Figure S7c-d). This demonstrates that the decrease in skill in this re-
 313 gion is mainly a result of changes to seasonal variability. In the North Atlantic, the in-

crease in skill is still seen, but to a reduced degree when the lower frequencies are removed (Figure S7e-f). This suggests that seasonal variability is playing a role in subseasonal prediction skill changes in this region, however, there is also likely a contribution from subseasonal variability to these changes. This is consistent with research that suggests the North Atlantic may become more sensitive to MJO teleconnections in the future (Samarasinghe et al., 2021).

The influence of seasonal variability on subseasonal prediction skill changes can be further examined in the North Pacific and North Atlantic by training the neural networks to instead predict the sign of unfiltered z500 anomalies on seasonal lead times. In the North Pacific, we find that *changes* in skill at 60 and 90 day leads are similar to that for a lead of 21 days. This again implies that the changes in subseasonal prediction skill seen in the North Pacific are due to changes in seasonal variability. In the North Atlantic, the change in skill for the seasonal lead time is larger than the 21 day lead time. This difference in the change suggests that the network is focusing on different sources of predictability for the 21 day prediction compared to the 60 or 90 day predictions, implying again that the change in skill in the North Atlantic is not purely due to seasonal variability changes in the future (Figure S8-S9).

4 Conclusions

While accurate subseasonal predictions are important for society (White et al., 2021), this timescale is known to exhibit limited predictability (Vitart et al., 2017). One method to improve prediction skill on subseasonal timescales is to utilize Earth system states which are known to provide enhanced subseasonal predictability when they are present (forecasts of opportunity; Mariotti et al., 2020). Previous research has examined how specific Earth system states important for subseasonal prediction (e.g. MJO and ENSO) and their teleconnections may change in a warmer climate (e.g. Maloney et al., 2018; Cai et al., 2021; J. Wang et al., 2022). To address whether these projected changes ultimately impact subseasonal predictability, we use the CESM2-LE and simple artificial neural networks to quantify and understand how subseasonal predictability provided by the tropics may change in a warmer climate. We find that there are changes to subseasonal prediction skill across the Northern Hemisphere and the largest differences in skill mainly occur during forecasts of opportunity.

Our results are supported by recent research on changes to MJO and ENSO teleconnections. In particular, the increase in skill along the west coast of North America is consistent with the projected eastward shift of MJO and ENSO teleconnections in the future (e.g. Jenney et al., 2021; J. Wang et al., 2022; Fredriksen et al., 2020; Beverley et al., 2021). In addition, our results suggest there is a contribution from both subseasonal and seasonal variability changes to the increase in prediction skill in the North Atlantic. This is consistent with research suggesting the North Atlantic becomes more sensitive to the MJO (Samarasinghe et al., 2021) and ENSO (Drouard & Cassou, 2019; Fereday et al., 2020) in the future. We also identify a substantial decrease in skill over the North Pacific and from our analysis, hypothesize that this decrease is mainly driven by a reduced influence of ENSO teleconnections to this region in the future. Overall, while both MJO and ENSO teleconnections are projected to change in the future, our analysis demonstrates that changes to ENSO and its teleconnections (e.g. seasonal variability) at least partially explain substantial changes in subseasonal prediction skill across the Northern Hemisphere in the CESM2-LE. Changes to subseasonal variability may still play a role in changes to subseasonal prediction skill in certain locations (e.g. North Atlantic), but further work is needed to understand and quantify its contribution. In addition, we only explored the Niño 3.4 index as a metric for ENSO variability, and future work could further extend this to other metrics that capture ENSO dynamics and that may also account for possible changes in ENSO variability under climate change.

Using the CESM2-LE, we show that neural networks are a useful tool for identifying and understanding future changes in predictability. In addition, we find that changes in subseasonal prediction skill across the Northern Hemisphere are often largest during forecasts of opportunity, suggesting that future research on prediction skill changes should focus on periods of enhanced predictability. While this research addresses changes in boreal wintertime subseasonal predictability provided by the tropics, future research should also examine how other seasons and sources of predictability may be affected in a warmer climate. This could include identifying possible changes to the importance of the stratosphere for subseasonal prediction or changes to boreal summer subseasonal predictability due to changes to the importance of the boreal summer intraseasonal oscillation (B. Wang & Rui, 1990). Furthermore, although this work examines subseasonal predictability changes by the end of the century, examining how quickly these changes may be detected is also worthy of study. Ultimately, this research demonstrates the utility of neural networks to quantify and gain physical insight into changes in subseasonal predictability in future climates.

Open Research

CESM2 Large Ensemble data (precipitation, SSTs and z500) are provided by the University Corporation for Atmospheric Research/National Center for Atmospheric Research (<https://www.cesm.ucar.edu/projects/community-projects/LENS2/data-sets.html>).

Acknowledgments

This research is partially funded by the NSF Graduate Research Fellowship under grant 006784 and partially funded by the Regional and Global Model Analysis program area of the U.S. Department of Energy’s Office of Biological and Environmental Research as part of the Program for Climate Model Diagnosis and Intercomparison project.
