Key Points:

- Micron-scale crack network evolution and localization is imaged *in-situ* in deforming granite samples with controlled initial heterogeneity

- Heterogeneity affects order and predictability of the phase transition to failure, which occurs as correlation length approaches grain size

- Correlation dimension of the crack population is a key indicator of localization, and anisotropy in starting porosity dictates fault strike

Abstract

Catastrophic failure of brittle rocks is important in managing risk associated with system-sized material failure. Such failure is caused by nucleation, growth and coalescence of micro-cracks that spontaneously self-organize along localized damage zones under compressive stress. Here we present x-ray micro-tomography observations that elucidate the *in-situ* micron-scale processes, obtained from novel tri-axial compression experiments conducted in a synchrotron. We examine the effect of microstructural heterogeneity in the starting material (Ailsa Craig micro-granite; known for being virtually crack-free) on crack network evolution and localization. To control for heterogeneity, we introduced a random nano-scale crack network into one sample by thermal stressing, leaving a second sample as-received. By assessing the time-dependent statistics of crack size and spatial distribution, we test the hypothesis that the degree of starting heterogeneity influences the order and predictability of the phase transition between intact and failed states. We show that this is indeed the case at the system scale. The initially more heterogeneous (heat-treated) sample showed clear evidence for a second-order transition: inverse power-law acceleration in correlation length with a well-defined singularity near failure, and distinct changes in the scaling exponents. The more homogeneous (untreated) sample showed evidence for a first-order transition: exponential increase in correlation length associated with distributed damage and unstable crack nucleation ahead of abrupt failure. In both cases, anisotropy in the initial porosity dictated the fault orientation, and system-sized failure occurred when the correlation length approached the grain size. These results have significant implications for the predictability of catastrophic failure in different materials.

Plain Language Summary

When rocks deform, tiny cracks appear, increasing in size and number until the rock breaks completely, often along a narrow plane of weakness where cracks have spontaneously aligned. Sometimes, when the microstructure is complicated, cracking accelerates quickly in a predictable way, giving a good indication of when the rock will break. In other cases, when the microstructure is more uniform, cracking accelerates more slowly and the rock breaks suddenly and early. To understand why failure is predictable in some cases but not others – a major problem in managing risk from material failure (e.g., earthquakes) – we used x-ray imaging to see how cracks form and interact with each other inside deforming rocks. We found that predictable behavior only arose when cracks aligned themselves asymmetrically. The orientation of this damage zone was governed by the rock's pre-existing microstructure. We also found distinct changes in crack size and spatial arrangement during alignment, indicating that the rock was approaching failure. However, when cracks did not align asymmetrically, similar changes were not observed and failure was not predictable. Our results are important because they help explain why reliable indicators of catastrophic failure are not always observed and why forecasting may only work in certain cases.

53   **List of Symbols (in order of appearance)**

variable	symbol
correlation length (typical linear dimension of largest void)	ξ
time	t
critical (failure) time	t_c
axial sample strain	ϵ
critical (failure) strain	ϵ_c
strain rate	$\dot{\epsilon}$
differential stress	σ
axial stress	σ_1
confining pressure (radially-symmetric)	σ_3
sample length	L
critical (failure) stress	σ_c
sample co-ordinate system	x, y, z
dip	ϕ
strike	θ
porosity	φ
number of segmented voids	N
individual void	i
volume of an individual void (pore or micro-crack)	V_i
volume of the largest void	V_{max}
sample radius	R
length of analyzed sub-volume	l
volume of analyzed sub-volume	V_{subvol}
corrected Akaike Information Criterion	$AICc$
first-order moment of inertia (void centroid)	M
second-order moment of inertia (covariance matrix)	I
void ellipsoid radius	r
mean void ellipsoid radius	$\bar{r}$
power-law exponent of void volume distribution	β
Euclidean distance between two voids (inter-void distance)	L_i
two-point correlation (fractal) dimension (power-law exponent of inter-void distance distribution)	D
cumulative complementary (survivor) function of frequency-volume distribution	$\Phi(V)$
completeness threshold of frequency-volume distribution	V_t
tapering corner threshold of frequency-volume distribution	V_c
modified Bayesian Information Criterion	BIC
incremental probability distribution of inter-void lengths	$P(L_i)$
exponent of incremental inter-void length distribution	D_{inc}

54

1 Introduction

55
56   Catastrophic failure of rocks in the brittle Earth is a critically-important driving mechanism
57 for phenomena such as landslides, volcanic eruptions and earthquakes, including induced
58 seismicity. Such failure often happens suddenly and with devastating consequences, occurring
59 when structural damage, in the form of smaller faults and fractures, concentrates within localized
60 zones. Damage localization leads to weakening and stress redistribution, eventually resulting in
61 system-sized brittle failure along a distinct and emergent fault plane. Localized damage is
62 pervasive at all scales throughout the brittle crust (Mitchell and Faulkner, 2012) and is therefore a
63 fundamental control on catastrophic failure. Crack nucleation and growth, and crack coalescence
64 within already localized zones, are relatively well-understood from microstructural and field
65 observations of damaged rocks, and from monitoring and locating earthquakes and acoustic
66 emissions (elastic wave packets released during laboratory-scale micro-fracturing events).
67 However, the process of localization remains elusive. Smaller cracks spontaneously self-organize
68 along the incipient fault plane, often immediately before failure, but the precise mechanisms
69 involved in this self-organization have yet to be determined. Open questions include: (i) how do
70 cracks, pores and grain boundaries interact locally with the applied stress field to cause
71 catastrophic failure to occur at a specific place, orientation and time? (ii) why can we detect
72 precursors to catastrophic failure only in some cases?

73   Fractures and faults have a self-similar structure; they are scale-invariant in their length
74 and spatial distributions (Main et al., 1990; Main, 1996; Bonnet et al., 2001), and in the way their
75 size relates to the energy released during rupture (Abercrombie, 1995; Goodfellow and Young,
76 2014). Remarkably, earthquakes and acoustic emissions (AE) are indistinguishable apart from the
77 absolute source size, with scaling characteristics that are invariant over 15 orders of magnitude
78 (Goodfellow and Young, 2014). This behavior is controlled by the local stress state and rock mass
79 properties. Classically, brittle rock deformation and failure have been characterized by AE, with
80 progressive cracking in heterogeneous materials under stress leading to systematic changes in the
81 AE event rate and its frequency-magnitude distribution. Experiments have shown that pervasive
82 microcracking accumulates in the sample sub-critically, i.e., without causing system-sized failure
83 (Lockner et al., 1991; Lei et al., 2000), until the accumulating cracks self-organize along an
84 asymmetric, localized damage zone. System-scale failure then occurs when nucleating micro-
85 cracks have localized sufficiently for a runaway positive feedback of self-sustaining crack
86 propagation and coalescence to take over (Main et al., 1993). In some cases, this self-organization
87 becomes evident in the emergence of an inverse power-law acceleration of event rate with a well-
88 defined failure time. In others, system-sized failure of rock samples is commonly associated with
89 the transition from an exponential increase to a sudden, rapid acceleration in the AE event rate
90 close to peak stress (Sammonds et al., 1992; Moura et al., 2005; Vasseur et al., 2015). This
91 transition occurs exactly when cracks begin to localize along the incipient fault plane (Lockner et
92 al., 1991). At this crucial point, nucleated cracks grow by jumping geometrical and rheological
93 barriers, so regions of stress concentration must already be correlated at the scale of the incipient
94 fault network (Sammis and Sornette, 2002). The organized fracture network then propagates
95 dynamically, with macroscopic failure occurring at a well-defined, finite time as the power-law
96 reaches its asymptote.

97   This behavior indicates a transition from pervasive but stable crack growth, controlled by
98 the sample's microstructure, to an unstable regime of dynamic rupture along an organized fracture
99 network, controlled by stress and fracture mechanics (Guéguen and Schubnel, 2003; Alava et al.,

100   2008). The inverse power law transition can be described as a critical or second-order phase
101   transition; a continuous transition from one state to another, during which the system becomes
102   extremely susceptible to external factors. It is second-order if the first derivative of the free energy
103   of the system (an entropy term) changes continuously as a function of the control parameter, e.g.,
104   temperature (Stanley, 1971, Fig. 2.6) or, in the case of a constant strain (or stress) rate rock
105   deformation experiment, strain (or stress). This is associated with an inverse power law
106   acceleration of the correlation length towards the critical point (Bruce and Wallace, 1989). At this
107   point, strong correlations exist between all parts of the system (including at long-range) and many
108   length scales become relevant (resulting in a self-similar structure and power-law scaling), with
109   events occurring at all relevant length scales (associated with broadband self-similarity of
110   correlations). The transition to an inverse power-law in the AE event rate, with its 'finite-time
111   singularity' at failure, is also characteristic of a second-order or critical phase transition (Sammis
112   and Sornette, 2002). If this occurs in the lead up to macroscopic failure, then the failure time can
113   be forecast accurately (Vasseur et al., 2015; 2017). Inverse power-law acceleration to a well-
114   defined failure time has also been seen in the evolving microstructure (micro-crack porosity and
115   the volume of the largest micro-fracture) of crystalline rocks undergoing brittle deformation
116   (Renard et al., 2017; 2018).

117   However, the evolution of damage does not always allow a fit to a model with a well-
118   defined failure time. In structurally homogeneous materials, there is no emergent, smooth power-
119   law acceleration to failure, as shown experimentally by Vasseur et al. (2015; 2017) for a range of
120   rock types and material analogues. In the extreme case of a single flaw in an otherwise uniform
121   starting material, there is no precursor, and catastrophic system-sized failure occurs suddenly when
122   the flaw propagates dynamically at a maximum in the system free energy. In turn, this depends on
123   the applied stress, the length of the starting flaw, and the specific surface energy of the material
124   (Griffith, 1921; 1924). This results in a discontinuous or first-order transition between intact and
125   failed states. In real materials that possess only a small amount of microstructural disorder,
126   progressive subcritical cracking, i.e., cracking which does not fulfil the conditions for sustained
127   propagation, shows only an exponential increase in the event rate time-to-failure behavior (Vasseur
128   et al., 2015; 2017). Failure occurs suddenly and early; often much earlier than expected from an
129   exponential asymptote (Vasseur et al., 2015; 2017). This behavior is also characteristic of an abrupt
130   first-order transition, with the exponential behavior reflecting local correlations (Stanley, 1971;
131   Sethna, 2006).

132   Phase transitions are often characterized by the evolution of the correlation length and
133   scaling exponents of the system in question (Stanley, 1971). The correlation length, ξ, is the
134   distance over which the effects of a local perturbation of the system will spread (Thouless, 1989).
135   Close to a critical point, the system can be viewed as made up of regions of size ξ in the critical
136   state. In this case, ξ can be interpreted as the size of the regions of the nucleating phase, or the
137   typical linear dimension of the largest piece of correlated spatial structure (Bruce and Wallace,
138   1989), which in our case is approximately the length of the largest fracture. As the two phases
139   (intact and failed) compete to select the final equilibrium state, regions closer than ξ are correlated
140   and those further apart are uncorrelated. Approaching the critical point, the correlated (nucleating)
141   regions become comparable to the system size. Thus, the maximum correlation length, and
142   associated parameters such as the maximum AE magnitude, are restricted by the system size.

143   During a first-order transition, the correlation length ξ becomes macroscopically large but
144   remains finite until the discontinuity at the sudden change of state (Stanley, 1971). In the case of

145 a single Griffith crack, the correlation length is simply the length of the starting flaw, which
146 suddenly becomes system-sized at failure as the flaw propagates instantaneously through the
147 material (Figure 1, blue line). When real, structurally homogeneous materials, with a dilute
148 population of material flaws, undergo progressive subcritical cracking (e.g., Vasseur et al., 2015;
149 2017), we expect the correlation length to increase exponentially but remain finite until it becomes
150 system-sized at a sudden-onset discontinuity (Figure 1, orange line). Conversely, during a
151 continuous phase transition, the correlation length ξ becomes effectively infinite (Figure 1, green
152 line), growing as an inverse power-law function of the control parameter (e.g., temperature), T,
153 approaching the critical point, T_c (Bruce and Wallace, 1989):

$$\xi \sim (T_c - T)^{-\nu} \qquad (1)$$

154 This is the type of behavior associated with progressively more heterogeneous materials
155 undergoing brittle deformation (Vasseur et al., 2015; 2017). In summary, the degree of
156 microstructural disorder of a material exerts a strong control on the type of phase transition from
157 subcritical crack growth to dynamic rupture, and consequently the predictability of the transition.
158 In particular, experiments (Vasseur et al., 2017) and models (Kun et al., 2018) have shown that
159 heterogeneity strongly influences the spatial distribution of micro-cracks at failure.

160 Here we investigate the impact of material heterogeneity on the nature of the phase
161 transition between intact and failed states, and the associated predictability of failure, at the
162 micron-scale. We show how the micro-crack network evolves within a deforming crystalline rock
163 with different amounts of disorder. Since pre-existing cracks are the most dominant factor of all
164 heterogeneities that govern the fault nucleation process in laboratory rock samples (Lei et al.,
165 2000), we deformed two samples of Ailsa Craig micro-granite: one being an as-received control
166 (nominally crack-free), and the other containing a pre-existing nano-scale crack network, induced
167 by thermal stress, as a proxy for increased heterogeneity. Ailsa Craig samples, as received from
168 the quarry, have no detectable cracks on thin sections under both optical and scanning electron
169 microscopes (Meredith et al., 2005; 2012). They are an extreme end member of lowest crack
170 density in natural rocks. Through the analysis of 4D, *in-situ* synchrotron x-ray micro-tomography
171 (µCT) images of the two samples undergoing tri-axial deformation (see Cartwright-Taylor et al.
172 (2020) for access to the dataset), we test the hypothesis that the transition to failure is abrupt and
173 unpredictable (first-order) in the as-received sample (our initially crack-free end member), but is
174 continuous and predictable (second-order) in the pre-cracked sample. *In-situ* observation of the
175 deforming microstructure allows us to measure directly the relevant parameters such as the
176 correlation length and the scaling exponents.

177 We find that increasing the microstructural disorder affects the geometry, size and spatial
178 distribution of the evolving micro-fractures. Using a combination of visual inspection of the µCT
179 images, geometrical analysis of the evolving crack network, and techniques used in statistical
180 seismology, we show that the micro-crack network evolution varies significantly between the two
181 samples. The degree of starting heterogeneity controls (i) the evolving spatial clustering and
182 anisotropy of the micro-cracks, and (ii) the order of the phase transition. The initially crack-free
183 sample exhibits an exponential increase in damage that reflects local correlations, a finite
184 correlation length, and no obvious precursors to failure. In contrast, the pre-cracked sample
185 exhibits emergent power-law behavior, an inverse power-law acceleration to infinite correlation
186 length and clear precursors to failure. However, though the parameters may be different, the
187 power-law scaling of the micro-crack volume and inter-crack length distributions, and some crack
188 growth characteristics, appear independent of heterogeneity. Allowing for the fact that such

189 microscopic failure characteristics may not be detectable above ambient noise in a field
190 experiment, this may explain why measureable geophysical precursors to catastrophic failure
191 events are detected only in some cases.
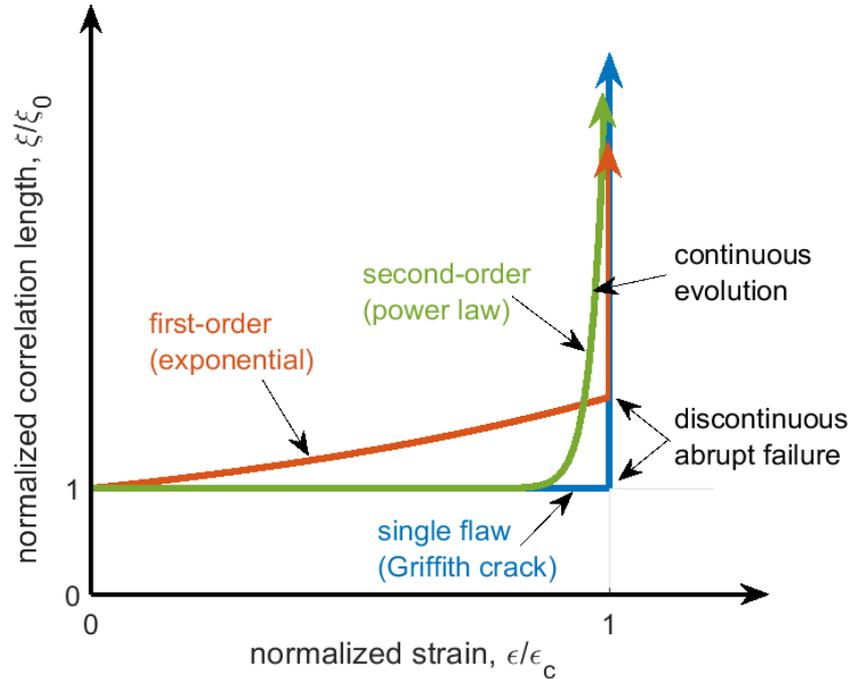

192

193 **Figure 1:** Schematic graph showing the expected behavior of the correlation length ξ,
194 normalized by its initial value ξ_0, as strain ϵ increases towards failure at critical strain ϵ_c for the
195 three phase transition cases described in the text. The Griffith crack (blue line) and the exponential
196 (orange line) are both examples of first-order transitions, exhibiting abrupt failure evident as the
197 discontinuity in ξ at ϵ_c. The inverse power-law (green line) shows the smooth, continuous
198 evolution to failure characteristic of a second-order transition.

199   **2   Materials and Methods**

200   **2.1   Ailsa Craig micro-granite and thermal stressing**

201   We used Ailsa Craig micro-granite (ACM) from the island of Ailsa Craig in the Firth of
202   Clyde, Scotland. ACM is an extremely rare type of silica-unsaturated, alkali-rich microgranite,
203   known as Blue Hone (Meredith et al., 2012). As received from the quarry, no pre-existing
204   microcracks are detectable either by optical or scanning electron microscopy (Meredith et al.,
205   2005; 2012). Porphyritic in texture with a groundmass of mean grain size 250 μm, ACM contains
206   sparsely distributed microphenocrysts (up to 1.5 mm) of alkali feldspar (Odling et al., 2007). Clint
207   et al. (2001) found it to have extremely low porosity (<< 1 %) and permeability (1.5 x 10^{-23} m^2 at
208   10 MPa effective pressure), indicating that the small amount of pre-existing pores are
209   predominantly unconnected (e.g., see Fig. 3 top left in Meredith et al., 2012). These properties
210   make ACM ideal both for its main commercial use as the running surface of curling stones, and
211   for the purposes of this study. We chose ACM for two main reasons: (i) its small grain size (250
212   μm) and (ii) its virtually crack-free nature. The former is essential to ensure a statistically
213   significant number of grains (>10 grains per diameter) in the small (3 mm diameter x 9 mm long)
214   cylindrical samples, and so to ensure that such small samples are representative of the rock as a
215   whole. The latter is essential to allow comparison between two extreme end-members: (i) an as-
216   received control sample with the lowest possible (to our knowledge) pre-existing crack density,
217   and (ii) a second sample (from the same small block) containing a thermally-induced crack
218   network imprinted over the nominally crack-free microstructure, thus increasing its heterogeneity
219   compared with the initially crack-free (untreated) sample.

220   To introduce a network of micro-cracks, one sample was heated slowly to 600 °C prior to
221   deformation. Thermal stressing is one of the key fracture-generating mechanisms in crustal rocks
222   and is an effective method for introducing micro-fractures into rock samples. Heating ACM to
223   elevated temperatures (>500 °C) induces significant, permanent micro-crack damage, evident from
224   photomicrographs (Meredith et al., 2012) and up to 50% and 30% reduction in P- and S- wave
225   velocities respectively (Clint et al., 2001). Scanning electron micrograph observations (Odling et
226   al., 2007) show that heating ACM to 900 °C causes the formation of a permanent micro-crack
227   network with average aperture of 0.3 μm formed by tensile failure, with each crack nucleating
228   halfway along a previous one to generate fracture intersections of primarily T-shaped geometry.
229   The thermally-induced crack network is not discernible in our μCT data because this aperture is
230   less than one tenth the length of one pixel (2.7 μm). Due to the partial volume effect, micro-cracks
231   with an aperture smaller than half a pixel are not visible (e.g., Voorn et al., 2013).

232   **2.2   Experimental apparatus, sample assembly and loading protocol**

233   Synchrotron x-ray microtomography (μCT), in combination with x-ray transparent
234   pressure vessels (e.g., Fusseis et al., 2014; Renard et al., 2016; Butler et al., 2017), allow the
235   microstructural evolution of deforming rock samples to be imaged directly, non-invasively and *in-
236   situ* during an experiment. This provides a critical advantage over conventional deformation
237   experiments, where the evolution of microscopic deformation cannot be inferred from post-test
238   analysis of the microstructure because it is heavily overprinted by extensive damage caused during
239   the macroscopic rupture process. Even in the case where conventional experiments are stopped
240   immediately prior to macroscopic failure, overprinting occurs when the hydrostatic and differential
241   stresses are released during extraction of the sample from the steel-walled pressure vessel,

242 resulting in permanent damage and hysteresis. *In-situ* x-ray μCT imaging overcomes both these
243 issues, as well as providing detailed microstructural information about the temporal evolution of
244 damage accumulation at a much higher temporal resolution. A single time-resolved experiment is
245 equivalent to tens of conventional experiments with *ex-situ*, post-experiment analysis, and has the
246 virtue that the same sample is observed at each time-step rather than a suite of samples, removing
247 the issue of sample variability.

248 In our experiments, each sample of ACM underwent tri-axial deformation to failure. The
249 experiments were conducted using a novel, miniature, lightweight (<1.3 kg) x-ray transparent tri-
250 axial deformation apparatus Mjölnir', developed and tested at the University of Edinburgh.
251 Mjölnir, named for the hammer of Thor, the Norse god of thunder, accommodates samples of 3
252 mm diameter and up to 10 mm in length and is designed to operate up to confining pressures of 50
253 MPa and axial stress in excess of 622 MPa (Butler et al., 2017). For this study, Mjölnir was
254 installed on the μCT rotation stage at the PSICHE beamline at SOLEIL Synchrotron, Gif-sur-
255 Yvette, France (Figure 2a,b). Two cylindrical samples of ACM, one heat-treated and one untreated
256 were cored using a diamond core drill and the ends ground flat and parallel to achieve 3 mm outside
257 diameter and 9 mm length, compared to the typical grain size of 250 μm. Even though this sample
258 diameter is very small (required to obtain high-resolution μCT images), the small grain size means
259 that there are more than 10 grains per diameter, ensuring that such small samples are representative
260 of the rock as a whole. The sample was assembled between the two pistons, jacketed with silicone
261 tubing (3.18 mm internal diameter and 0.79 mm wall thickness), and protected from the confining
262 fluid using twisted wire loops to seal the jacket against the piston (Butler et al., 2017). The pressure
263 vessel was lowered over the sample assembly and fixed into place. A confining pressure of 15
264 MPa was then applied and maintained during the test. A hydrostatic starting pressure condition
265 was achieved by simultaneously increasing the axial pressure to match the confining pressure.
266 Delivery of the pressurizing fluid, deionized water, to the hydraulic actuator and pressure vessel
267 was achieved using two Cetoni neMESYS^{TM} high pressure syringe pumps operated with
268 QmixElements^{TM} software.

269 Experiments were conducted at room temperature under nominally dry conditions. A
270 reference μCT scan was acquired at zero differential stress to obtain the initial state of the sample
271 prior to loading. The sample was then loaded to failure at a constant strain rate of 3 x 10^{-5} s^{-1} in a
272 step-wise manner, with steps of 20 MPa to start with, decreasing to 10 MPa from 70% of the failure
273 strength and then 5 MPa once the sample started to yield (Figure 2c). At each step the stress was
274 maintained and a μCT volume acquired. To accommodate the full sample length at maximum
275 resolution, three sequential scans were acquired at different positions along the length of the
276 sample and then stacked. For each position the corresponding projections that comprised the full
277 length of the sample were tessellated and merged to create a single projection used for
278 reconstruction of the whole sample in one μCT volume. Each full set of scans was acquired in
279 approx. 10 minutes. For each sample, 15 sets were acquired during loading with an additional set
280 acquired after the main failure. For the heat-treated sample, this included one set at peak
281 differential stress of 185 MPa. This μCT volume contained the incipient fault at the critical point
282 of failure, and the sample failed immediately upon continuation of the loading procedure. The
283 untreated sample reached a peak stress of 182 MPa but failed before it could be scanned at this
284 stress. The last pre-failure scan was at 177 MPa (97% of the critical failure stress, σ_c).

285 The differential stress is $\sigma = \sigma_1 - \sigma_3$, where σ_1 is the axial stress (the product of the
286 measured ram pressure and the difference in area between the ram and the sample cross-section)

287 and σ_3 is the radially-symmetric confining pressure. Axial sample strain was calculated as $\epsilon =$
288 $\delta L / L_0$, where δL is the change in length of the sample between the starting µCT volume and the
289 volume of interest and L_0 is the initial length of the sample. It was obtained directly from the
290 reconstructed µCT volumes by measuring the length change of the rock core between two fixed
291 locations in each volume.
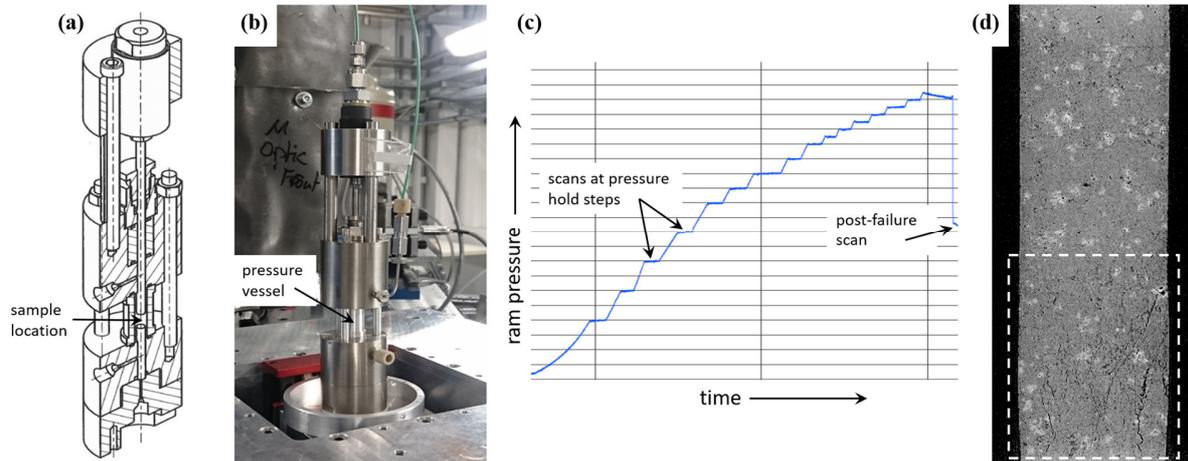

292

293 **Figure 2:** Our x-ray transparent deformation apparatus, Mjölnir, in (**a**) schematic (Butler
294 et al., 2017), and (**b**) installed at the PSICHE beamline. (**c**) Stepped loading procedure. (**d**)
295 Reconstructed µCT image showing damage accumulation at one end of the sample (this occurred
296 in both samples) – dashed white line shows the analyzed sub-volume.

2.3   X-ray imaging and image data pre-processing

298 X-ray µCT data was acquired using an sCMOS (scientific Complementary-Metal-Oxide
299 Semiconductor) Hamamatsu ORCA Flash4.0 camera, with a Rodagon 50 lens, giving about 2.5x
300 magnification (effective pixel size 2.7 µm), and a 250 µm thick LuAG:Ce scintillator. The white
301 beam with an average detected energy of about 66 keV was filtered with 1 mm aluminium and 0.5
302 mm tungsten. During each scan, 1200 projections were acquired over 180°, with an exposure time
303 per projection of 15-19 ms depending on the progressive darkening of the objective lens. A mix of
304 absorption and phase contrast data was acquired, with a sample to detector distance of 125 mm.

305 Each µCT volume was reconstructed by filtered back projection. Reconstructions were
306 performed at the PSICHE beamline, using both x-ray absorption and phase contrast modes as
307 implemented in the PyHST2 software (Mirone et al., 2014), and yielded 3D volumes of 1700 x
308 1700 x 4102 equidimensional voxels, with a voxel edge length of 2.7 µm. These volumes were
309 then processed to extract the fracture network from the reconstructed images. To deal efficiently
310 with the huge size of each 3D volume (approx. 40 GB) and speed up the subsequent processing,
311 we selected a sub-volume of interest – the region in the failed samples where the majority of
312 damage had accumulated (Figure 2d, Table 1). Using the Avizo™ software package, this sub-
313 volume was extracted from each of the full 3D volumes and de-noised with an anisotropic diffusion
314 filter (stop value 0.4 over 4 iterations), which was chosen to emphasize the microcrack features as
315 it preserves strong edges and enhances edge contrast. It was then down-sampled to 16-bit with a
316 32-bit threshold range of -0.3 to 0.8, yielding individual datasets of manageable size (approx. 3
317 GB).

318 **Table 1:** Dimensions of the whole sample and analyzed sub-volume, with uncertainties to
319 two decimal places.

sample	sample diameter (mm)	sample length (mm)	ROI length (mm)	ROI area (mm^2)	ROI volume (mm^3)
untreated [ACfresh02]	2.96	8.73	3.33	6.62	22.03
heat-treated [ACHT01]	2.97	9.46	2.71	6.58	17.83

320 ## 2.4   Segmentation

321   Each dataset of 3D grey-scale images was then segmented to separate from the rest of the
322 rock matrix the pre-existing pores and the evolving deformation-induced cracks in a binary
323 fashion. Herein we use the term 'porosity' to include all the segmented void space in the sample,
324 whether pre-existing (and therefore associated with the igneous history of the rock) or
325 deformation-induced. We use the term 'void' to describe an individual segmented object.

326   Although easily distinguishable by the human eye, narrow planar features such as fractures
327 are difficult to extract automatically from large 3D image datasets. This is due to the range of
328 greyscale values accommodated by fractures of different apertures and the increasing similarity of
329 these grey-values to the surrounding rock matrix as the aperture decreases. The main reason for
330 this is the partial volume effect, whereby voxels containing both air and rock matrix appear brighter
331 than voxels containing air alone. Fracture surface roughness and narrow apertures contribute to
332 this effect. We used a multiscale Hessian fracture filter (MSHFF) technique to meet these
333 challenges while still using an automated approach and segment the micro-cracks from the image
334 data. This technique, developed and described in detail by Voorn et al. (2013), uses the Hessian
335 matrix (second-order partial derivative of the input image data) to represent the local curvature of
336 intensity variation around each voxel in a 3D volume (e.g., Descoteaux et al., 2005). Attributes of
337 this local curvature can be used to distinguish planar features in the dataset (Text S1a in our
338 Supporting Information, SI). The analysis is conducted over a range of observed crack apertures,
339 which are combined to produce the final multiscale output: narrow fractures of varying apertures
340 detected within the 3D image data. The analysis was carried out using the macros for FIJI
341 (Schindelin et al., 2012) published by Voorn et al. (2013), utilizing the FeatureJ plugin (Meijering,
342 2010) to calculate the Hessian matrices, with input parameters given in (Table 2).

343   **Table 2:** Input parameters for segmentation code. Definitions given in Voorn et al. (2013).

smin	smax	sstep	blocksize	avgmat	consthresh	maxmat	padding	mincal	maxcal
2	8	1	1037	65535	0	56540	0	0.14118	0.32549

344   The binary segmented volumes were labelled and an intensity radius threshold of 15 to 100
345 applied followed by a small spot filter to remove round segmented objects with a radius of <50
346 pixels (134 μm) for visual clarity of the fault plane (Figure 3a). The local aperture at each voxel
347 of the segmented voids was computed from the diameter of the largest ball containing the voxel
348 and entirely inscribed within the object (Hildebrand and Ruegsegger, 1997). Even with the
349 segmentation method described, there is still significant under-sampling of the void population,
350 particularly at the narrower end of the aperture range (Figure 3b). Further work in this area is
351 required and would benefit from machine learning approaches (Andrew, 2018).

352   We present the data according to a co-ordinate system (x, y, z) where z is the vertical axis,
353 which is parallel to the loading direction and corresponds to the direction of axial stress (σ_1). The
354 other two (x and y) are the horizontal axes, which are perpendicular to the loading direction and

355 correspond to the confining stress ($\sigma_2 = \sigma_3$) with their directions arbitrarily assigned but consistent
356 between the two experiments. Void orientations are given in terms of their dip ϕ (deviation from
357 horizontal) and strike θ (deviation from y).
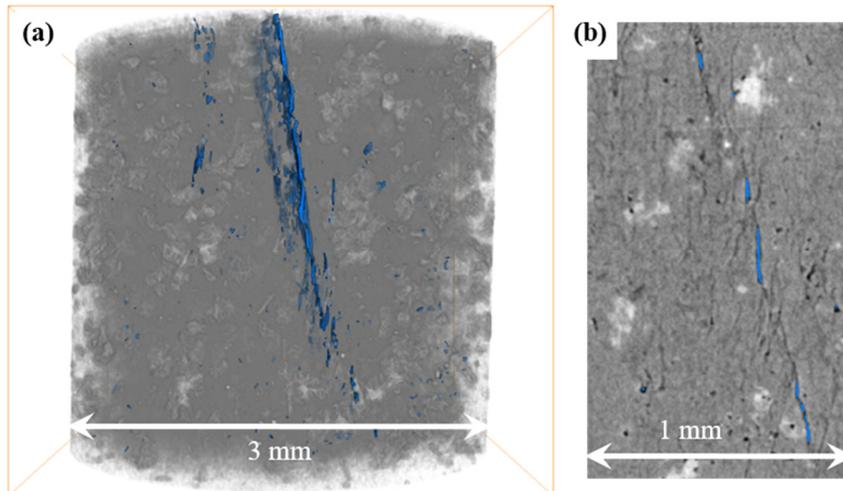

359 **Figure 3:** (**a**) Segmented fracture network (blue) within a greyscale 3D μCT sub-volume
360 at peak stress in the heat-treated sample. (**b**) Example of a 2D grey-scale slice, also with segmented
361 fractures highlighted in blue. Most of the very narrow fractures remain undetected due to the
362 similarity of the grey-scale values with the surrounding material.

363 **2.5   Analysis of the segmented microcrack network**

364 *2.5.1   Porosity and the number of fractures*

365 Initially of interest is the evolution of porosity, φ (including both the pre-existing pores
366 and the developing micro-cracks) and the total number of voids, N, in each 3D sub-volume as
367 deformation progressed. Due to the irregular shape of the segmented objects, and to take into
368 account crack coalescence, one void was defined as all objects that were connected at least by the
369 apex of a corner. To obtain N, each individual void, i, was assigned a label using the Label
370 Analysis module in Avizo^{TM}. Porosity was obtained from the total void volume divided by the
371 analyzed sub-volume: $\varphi = (\sum V_i)/(\pi R^2 l)$, where V_i is volume of each crack, R is the sample
372 radius and l is the length of the analyzed sub-volume. To determine the most likely empirical
373 relationship with strain for both φ and N, we found the parameters for several possible models
374 (quadratic, exponential and simple power-law) using non-linear least-squares regression and then
375 used the corrected Akaike Information Criterion, $AICc$ (Hurvich and Tsai, 1989) to test these
376 competing models objectively (see Text S2 in the SI for a full description of the calculations).

377 *2.5.2   3D micro-crack orientations and geometries*

378 These were obtained from the binary segmented data using an object-based approach to
379 determine the best-fitting ellipsoid around each segmented void (pore or micro-crack). Each
380 ellipsoid was calculated independently from the crack's 3D moments of inertia (Text S1b in SI),
381 also using the Label Analysis module in Avizo^{TM}. First-order moments, M, define the void's center
382 of mass (centroid). Second-order moments, I, define the inertia (or covariance) matrix, with
383 eigenvectors representing the ellipsoid axes orientations. Major, minor and medium ellipsoid radii,

384 r, were computed as $r = \sqrt{5|\text{eigenvalue}|}$ from each corresponding eigenvalue of the inertia
385 matrix (Ollion et al., 2013).

2.5.3 Crack network scaling exponents and correlation length

387 To find evidence for the type of phase transition undergone by each sample, we obtained
388 the following indicators of critical point behavior: the correlation length, ξ (linear dimension of
389 the largest void), the void size exponent, β, and the void separation exponent, or correlation
390 dimension, D. These time-dependent parameters are equivalent to those commonly used to
391 quantify the evolution of seismicity from acoustic monitoring (Aki, 1965; Sykes and Jaumé, 1990;
392 Bufe and Varnes, 1993; Sornette and Sammis, 1995; Turcotte, 1997; Ouillion and Sornette, 2000;
393 Zöller et al., 2001; Kagan, 2002; Sammis and Sornette, 2002; Tyupkin and Giovambattista, 2005).
394 In rock deformation studies (e.g., Moura et al., 2005; Lei and Satoh, 2007), these parameters have
395 been similarly inferred from the amplitudes and locations of acoustic emissions (AE). In particular,
396 the inter-crack distance inferred from AE is a key parameter that controls the failure time and
397 hence the accuracy of failure-time forecasts (Vasseur et al., 2017).

398 In this study, we obtained ξ, β and D directly from the evolving population of micro-cracks
399 in the µCT data, rather than indirectly from AE. We used void volume as a metric for void size
400 and estimated inter-void distances (void separation) from the distribution of points defined by
401 ellipse centroids. We obtained void volumes, V_i, and centroids (Text S1b in SI) directly from the
402 Label Analysis module in Avizo^{TM}, and then computed Euclidean lengths, L_i, between centroids.

403 We obtained maximum likelihood estimates of the void size exponent, β, from the
404 frequency-volume distribution in each µCT sub-volume. We tested three different but related
405 models often used to describe the seismic moment distribution in seismicity (Kagan, 2002 – full
406 details of this procedure are given in Text S3 in SI):

407 (i) GR: the Pareto distribution (a pure power law, equivalent to the Gutenberg-Richter
408 distribution) with cumulative complementary (survivor) function $\Phi(V) = (V_t/V_i)^\beta$ for
409 $V_t < V_i < V_{max}$, where V_i is volume of each individual void and V_{max} is the upper bound
410 (maximum) void volume in the distribution.

411 (ii) TRP: the truncated Pareto distribution (similar to the GR but showing a power-law taper
412 in the tail towards V_{max}), with $\Phi(V) = [(V_t/V_i)^\beta - (V_t/V_c)^\beta]/[1 - (V_t/V_c)^\beta]$ for $V_t <$
413 $V_i < V_c$, where V_c is the tapering corner volume of the distribution.

414 (iii) TAP: the tapered Pareto distribution (equivalent to the modified Gutenberg-Richter
415 relation which shows an exponential taper in the tail towards V_{max}), with $\Phi(V) =$
416 $(V_t/V_i)^\beta \exp[(V_t - V_i)/V_c]$ for $V_t < V_i < \infty$.

417 We defined a correlation length, $\xi = \sqrt[3]{V_{max}}$ for the pure power-law model or $\sqrt[3]{V_c}$ for the
418 truncated models. The completeness volume, V_t, is the smallest void volume at which 100% of
419 voids in a space-time volume are detected (Rydelek and Sacks, 1989; Woessner and Wiemer,
420 2005; Mignan and Woessner, 2012), and is equivalent to the threshold of completeness in
421 seismicity data. We obtained V_t from the maximum curvature method (Roberts et al., 2015), i.e.,
422 from the peak of the incremental frequency-volume distribution. This method is appropriate for
423 the sharp-peaked distributions seen in our data (Figure S1 in SI). In both samples, the number of
424 voids with $V \geq V_t$ exceeded 200, which is the minimum catalogue size required for reliable
425 estimation of β (Roberts et al., 2015). We used a modified Bayesian Information Criterion (BIC)

426   (Leonard and Hsu, 1999; Bell et al., 2013a) to find the most appropriate model (see Text S3 for
427   full details of the calculation, and Figure S2 in SI for the full results) thus obtained the most likely
428   values of β and ξ for each distribution. The BIC is more appropriate for distributions of large
429   sample populations investigated here than the AIC, and the results can be compared more directly
430   with previous work (Bell et al., 2013a).

431   To distinguish the type of phase transition, i.e., whether or not ξ followed an inverse power-
432   law acceleration to failure, we fit the data by non-linear least-squares regression to an inverse
433   power-law model of the form: $y = k(x_p - x)^{-p}$, where x_p is the predicted value of the control
434   parameter x at failure, k is a scaling factor and p parameterizes the rate acceleration of y, all
435   determined by non-linear regression. The point of failure, x_p, is defined by a mathematical
436   singularity as $y \to \infty$. This is directly analogous to the approach to a critical point in a second order
437   phase transition for the correlation length (Equation 1). It is also equivalent to material failure
438   forecasting approaches based on the Time-Reversed Omori Law for aftershock decay (e.g., Voight,
439   1988; Cornelius and Voight, 1994; Utsu et al., 1995; Kilburn and Voight, 1998; Kilburn 2003;
440   Smith et al., 2009; Bell et al., 2013b; Vasseur et al., 2015; 2017). We used stress as the control
441   parameter instead of time because the stepped loading procedure that we conducted precludes
442   realistic temporal rate estimates. Importantly, this model makes no *a priori* assumptions about any
443   of the parameters. The predicted failure stress, σ_p, is what would be available in real time, rather
444   than the observed failure stress, σ_c. By estimating σ_p independently, we can quantify any
445   systematic error in its estimation by comparing it to the observed failure stress, and hence quantify
446   any bias in a potential forecasting scenario. We used a trust region algorithm to minimize the
447   residual sum of squares between the observed data and the model (see Text S5 in SI for details).
448   We also tested an exponential model $y = h \exp(qx)$ as an alternate hypothesis. We cannot use a
449   simple criterion such as r^2 alone to determine the relative goodness of fit because the competing
450   hypotheses have different degrees of freedom, so we used the corrected Akaike Information
451   Criterion ($AICc$ – see Text S2 in the Supporting Information for details of the calculations). It is
452   based on the residual sum of squares, and is considered more robust than r^2 alone because it takes
453   into account the number of parameters in the model, penalizes models with more parameters and
454   can be used to determine the relative likelihood of the models given the data.

455   We obtained the two-point fractal dimension, D, from the relation $P(L_i) \sim L_i^{D-1}$ (Turcotte,
456   1997), where $P(L_i)$ is the incremental probability distribution of the inter-void lengths, L_i (see
457   Text S4 in the SI for more detail). The exponent, $D_{inc} = D - 1$, of $P(L_i)$ in the identified power-
458   law region, $30 < L_i < 1350$ μm, was obtained from a linear regression in log-log space (Figure
459   S3 in the SI). D is then $D_{inc} + 1$. If $D < 3$, voids are clustered spatially but as $D \to 3$ they
460   become volume-filling, and therefore less clustered (Robertson et al., 1995).
461

462   **3   Results: Micro-fracture network evolution**

463   Here we present our 4D observations of the evolving segmented fracture network in each
464   sample, together with the distributions of micro-crack orientations. This is followed by results
465   from our quantitative analysis of the fracture network. We first show the influence of heterogeneity
466   on the evolution with strain of (i) stress, porosity and the number of voids, and (ii) void geometry,
467   which reveals how the initial, small anisotropy of the crack network increased in the lead-up to
468   failure. Following this, we test our hypothesis regarding the type of phase transition undergone by
469   each sample by showing the transition to failure of the correlation length as a function of stress.
470   Finally we present the evolution with strain of the correlation length and the scaling exponents of
471   void size and separation. For the purposes of testing our hypothesis and for clarity of presentation
472   we have analyzed data up to failure but not beyond.

473   **3.1   4D observations of micro-fractures and their orientations**

474   The spatial evolution of micro-cracks differs significantly between the two samples (Figure
475   4 and Figure 5). Although the untreated sample appeared to fail along a localized shear fault
476   (Figure 4P), pre-failure damage accumulated in a spalling pattern of radial damage zones sub-
477   parallel to σ_1 (Figure 4F-O). Conversely, the heat-treated sample failed along a localized shear
478   fault, inclined at 30° to σ_1, along which pre-failure damage had already accumulated (Figure 5K-
479   P). In both samples, the localized damage zones consisted mainly of shear and axial micro-
480   fractures oriented between 5° and 30° to σ_1 (Figure 6a,b) with bridging ligaments. Local fracture
481   aperture increased as fractures propagated within the localized zones of damage.

482   In the untreated sample, damage localization (established visually from the segmented CT
483   volumes in Figure 4) first occurred along four narrow zones simultaneously (orange ellipses in
484   Figure 4F) at 1.37% strain and 64% of the failure stress, σ_c, (Table 3). Damage was concentrated
485   along these zones until further radial zones developed on the other side of the sample (pink ellipses
486   in Figure 4J) at 85% σ_c. It is not clear exactly how the eventual fault developed because the sample
487   failed before the next scheduled image time. The post-failure μCT sub-volume (Figure 4P)
488   indicates that slip occurred along a plane not previously localized and located slightly above where
489   the radial damage had accumulated, which is consistent with the sudden, abrupt nature of the
490   failure inferred from the stress-strain data (Section 3.2.1). However, close to peak stress (97% σ_c;
491   Figure 4O) cracks had begun to localize along a shear zone that was above and formed from the
492   tip of some of the radial damage zones, and was conjugate to the eventual fault plane.

493   In the heat-treated sample, damage localization (established visually from the segmented
494   CT volumes in Figure 5) first occurred along a shear zone conjugate to the eventual fault plane
495   (orange ellipse Figure 5H) at 1.24% strain and 72% σ_c (Table 4). Damage progressively
496   concentrated along this plane until localization around the incipient fault plane became apparent
497   (pink ellipse in Figure 5K) at 90% σ_c and 1.38% strain; the same amount of strain as the initial
498   localization in the untreated sample. Fracture nucleation and propagation within the initial damage
499   zone then stopped, continuing instead along this more favorably-oriented zone until failure. This
500   flip in orientation between two optimally-oriented, conjugate, shear planes has previously been
501   seen by Lennartz-Sassinek et al. (2014). Here it coincides with reduced sample stiffness and strain
502   hardening inferred from the stress-strain data (Section 3.2.1).

503   Microcrack dips, ϕ, became progressively more vertical with increasing stress in both
504   samples (Figure 6a,b), indicating the preferential nucleation of tensile cracks. These cracks formed

505 en-echelon (Tapponnier and Brace, 1976; Kranz, 1979; Olson and Pollard, 1991; Reches and
506 Lockner, 1994) and wing-crack *(*Fairhurst and Cook, 1966; Nemat-Nasser and Horii, 1982; Horii
507 and Nemat-Nasser, 1985; 1986; Ashby and Hallam, 1986; Nemat-Nasser and Obata, 1988; Ashby
508 and Sammis, 1990) arrays (Figure 7), concentrated in the heat-treated case at the tip of the
509 propagating fault zone. All radial damage zones in the untreated sample grew in this manner
510 immediately after their initial localization (Figure 4F onwards). In contrast, this process occurred
511 only in the heat-treated sample during localization around the eventual fault plane (Figure 5L
512 onwards), not during the initial localization around the unfavorable conjugate. En-echelon and
513 wing-crack arrays formed at 1.45±0.01% strain in both samples (Figure 4G and Figure 5L). At
514 this point the untreated sample was only at 70% σ_c, compared to 90% for the heat-treated sample.

515   One advantage of the 3D sampling enabled by µCT imaging is that we can test the null
516 hypothesis that the initial sample porosity is isotropic. The optimal strikes of the segmented voids,
517 θ, show a predominant orientation in the initial porosity in both samples (Figure 6c,d). This starting
518 anisotropy was more pronounced in the heat-treated sample than in the untreated sample
519 (33.0±15.1% compared with 14.3±11.8% - see Table S1 in SI). Overall, anisotropy in the void
520 strike increased steadily throughout deformation in the heat-treated sample but remained
521 approximately constant in the untreated sample (Table S1 in SI). The strike of the eventual fault
522 closely followed this pre-existing anisotropy in both samples, but to a much greater degree in the
523 heat-treated sample. In the untreated sample, although the distribution peaks and troughs broaden
524 as the radial zones localized, the strike of the post-failure fault was oriented within 30° of the initial
525 preferred strike orientation (Figure 6c). In the heat-treated sample, the strike of the emerging fault
526 plane tracked the orientation of the initial crack porosity anisotropy almost exactly (Figure 6d),
527 while the distribution of peaks and troughs remained stationary, and became more defined, as the
528 damage zone localized.

529   Stereonet depictions (Figure 8) of the void orientations (poles to planes) projected along
530 the axial direction (σ_1) confirm these observations, showing a predominant strike parallel to the
531 pre-existing porosity in both samples, followed by the development of mainly vertical cracks at
532 localization, in line with our visual examination. These cracks initially cluster along the pre-
533 existing strike in both samples but become increasingly distributed in the untreated sample (blue
534 stereonets) during yield and approaching failure, with failure occurring along a fault offset by
535 around 30° to the pre-existing strike. Conversely, in the heat-treated sample (orange stereonets),
536 these vertical cracks cluster increasingly along the pre-existing strike throughout deformation.
537 Closure of some shallow-dipping voids is seen in both samples.

538   In the time-lapse video of the untreated sample in the x, y projection (Video S1 in the SI),
539 the first axial fracture initiated at a spot on the sample edge close to the bottom of the sample,
540 below and on the outside of a region of concentrated porosity. Further localization occurred
541 simultaneously along vertical zones distributed radially around the sample, which appear to have
542 grown preferentially into the sample before propagating vertically as crack segments linked up.
543 Approaching peak stress, an array of micro-cracks with varying orientations formed around the
544 region of concentrated initial porosity, bridging three radial zones in a curved damage zone. The
545 same process occurred again at 97% σ_c, bridging four radial zones adjacent to the previous three,
546 but in a conjugate orientation. This bridging fault propagated up the sample (Video S2 in the SI –
547 y, z projection), at a different strike to the post-failure fault.

548   Time-lapse video of deformation in the heat-treated sample in the x, y projection (Video
549 S3 in the SI) shows that localization initiated within the sample, not at the boundary, on the site of

550   a pre-existing void, precisely as anticipated by Griffith (1921, 1924). Subsequent micro-cracks
551   that localized along the damage zone nucleated between the initial site and the sample edge. The
552   emerging fault plane initiated at the sample boundary and grew horizontally into the sample, as
553   subsequent micro-cracks localized along it, before propagating down the sample parallel to the z, x
554   plane (Video S4 in the SI – y, z projection). Simultaneously, micro-cracks localized on the
555   opposite side of the sample along the same strike as the initial, arrested damage zone. As
556   deformation continued and the sample reached peak stress, micro-cracks nucleated in the center of
557   the sample. These cracks joined the optimally-oriented damage zone to the conjugate damage zone
558   on the other side of the sample, resulting in a curved shear zone, consisting of arrays of micro-
559   crack segments linked by bridges of intact rock, along which the sample failed.

Table 3: Differential stress, σ, and axial strain, ϵ, for each μCT sub-volume in the untreated sample [ACfresh02]. Letters A-P refer to the image volumes shown in Figure 4. Localization first appeared in scan F along several vertical zones distributed radially around the sample. Additional zones localized in scan J but scan P shows that failure occurred along an unrelated shear fault.

ACfresh02	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	failure	P

575   **Figure 5:** Projection in the y, z plane of segmented microcracks for the heat-treated sample
576 [ACHT01]. Orange ellipse indicates the onset of damage localization, pink ellipse indicates
577 localization along the emerging fault plane. Letters refer to the stress-strain steps in Table 4. Color-
578 coding shows the local fracture aperture at each voxel. See Figure S6 in SI for zip file of high
579 resolution images.

580
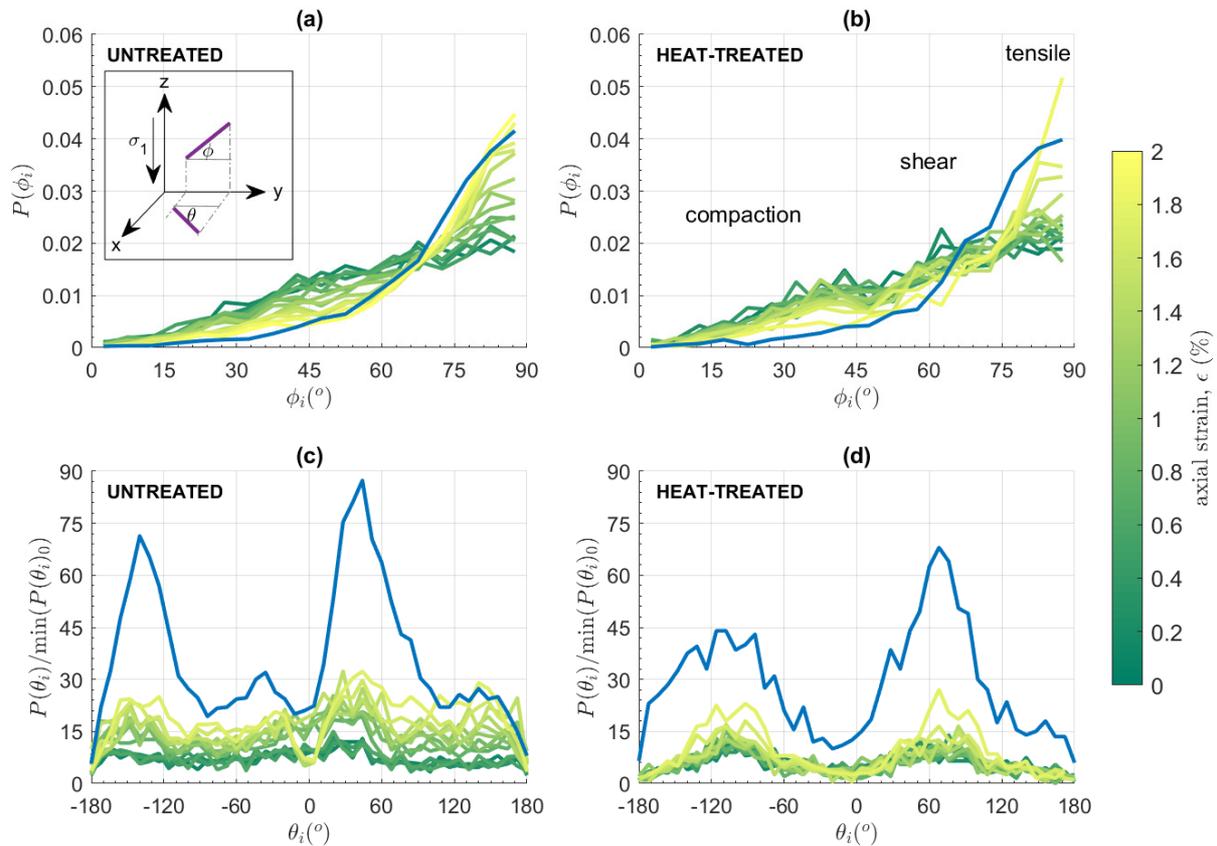

Figure 6: Void (**a,b**) dip ϕ and (**c,d**) strike θ probability distributions at each strain increment for (**a,c**) the untreated sample and (**b,d**) the heat-treated sample, calculated using the object-based best-fitting ellipsoid approach. Inset shows the measured angles with respect to the principal stress axes: $\phi = 90°$ is parallel to the z-axis, while $\theta = 0°$ is parallel with the y-axis. Labels on the dip distributions show the angles at which different damage mechanisms are prevalent. Strike distributions are normalized to the minimum $P(\theta)$ of the starting porosity. Blue distributions overlaying the rest are post-failure.

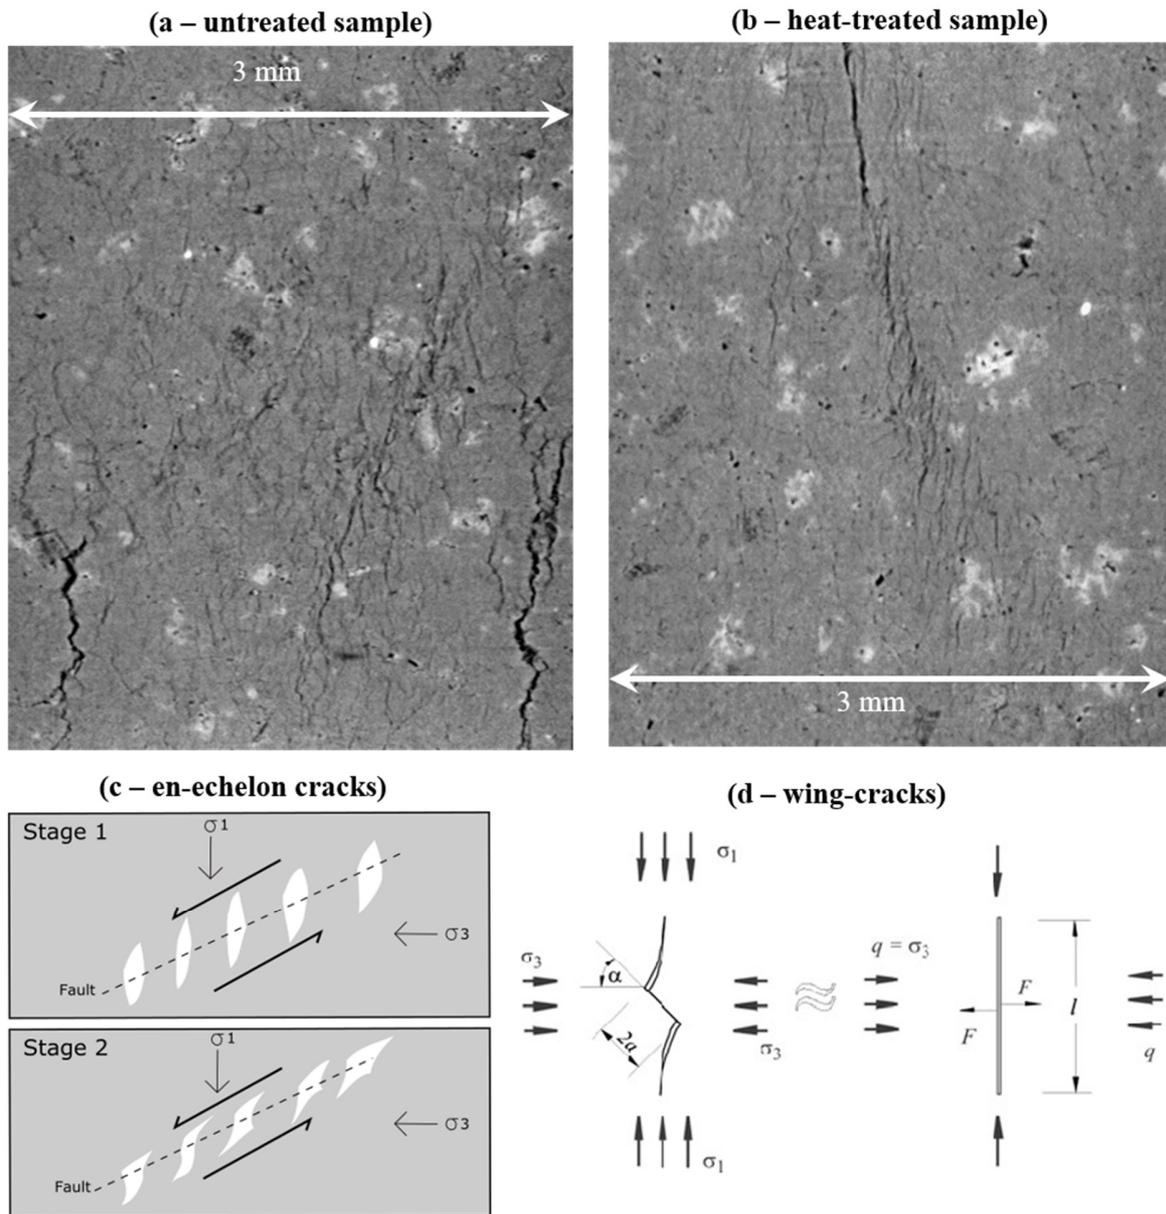

Figure 7: Slice through the sample in the y, z projection showing in (**a**) the untreated sample close to peak stress (Figure 4O) and (**b**) the heat-treated sample at peak stress (Figure 5O) the formation of tensile (**c**) en-echelon (Olson and Pollard, 1991; Thomas and Pollard, 1993) and (**d**) wing-cracks (Fairhurst and Cook, 1966; Fig. 15 in Damjanac and Fairhurst, 2010).
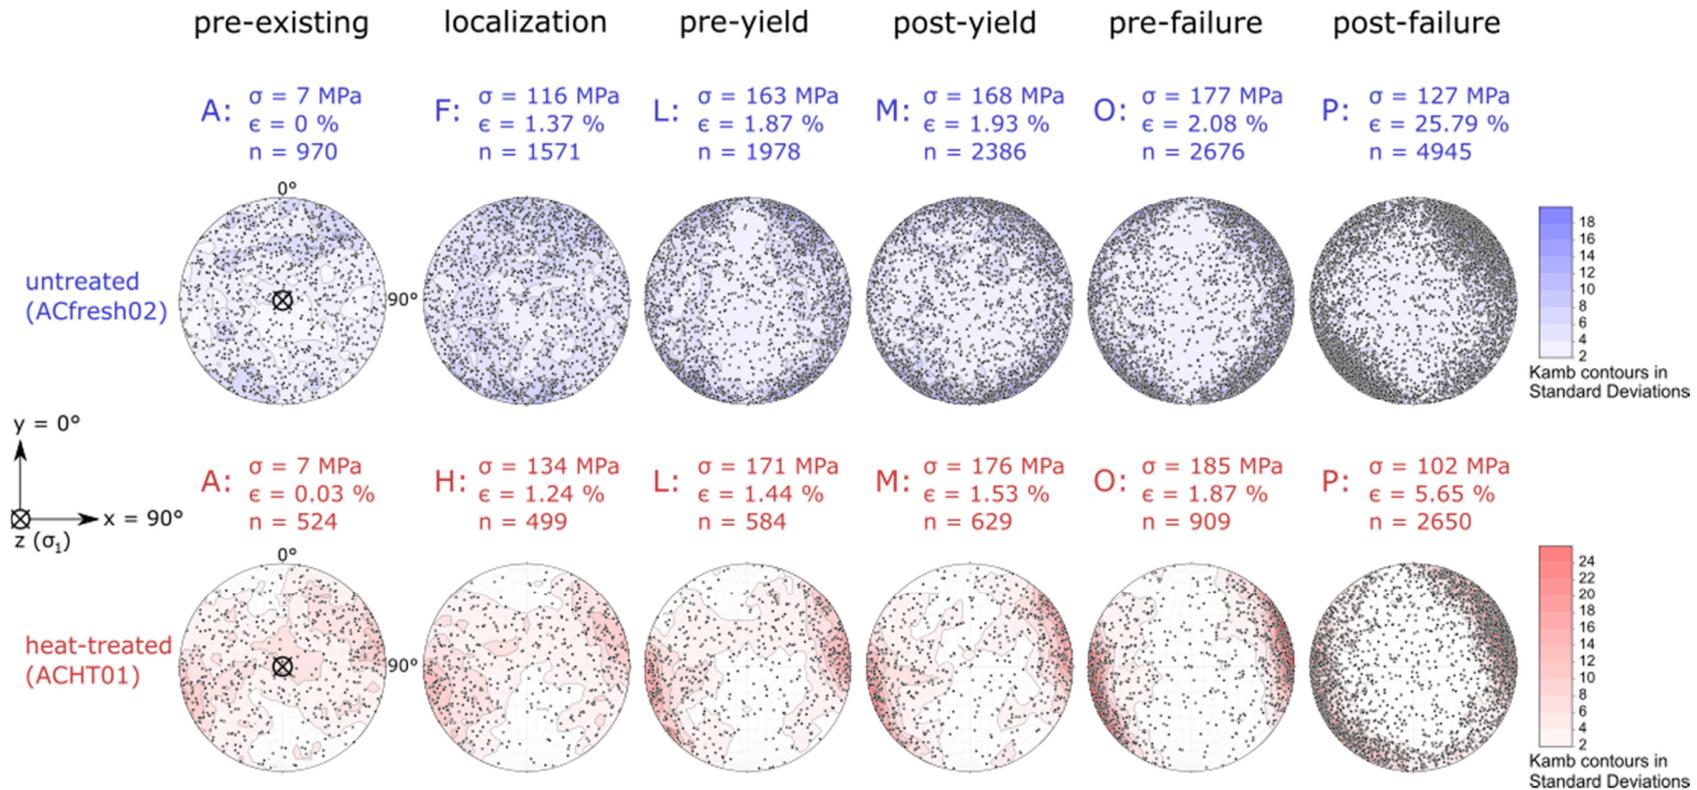

Figure 8: Stereonet projection of void ellipsoid orientations (poles to planes) projected down the loading axis (i.e., in the x, y plane) for both samples. Letters refer to the stress-strain steps for the untreated (Table 3 and Figure 4) and the heat-treated (Table 4 and Figure 5) samples. Clustering contours were calculated from uniform kernel density estimation to show significant departures from a uniform distribution (Kamb, 1959). Kernel radius, $r = 3/\sqrt{\pi(9 + n)}$, where n is the number of data points. Contour intervals are given as a multiple of the standard deviation to emphasize the statistical significance of the number of points falling into each kernel (Haneberg, 2004). In the untreated sample, strikes were dominated by the pre-existing porosity until scan F, when micro-crack localization initiated along the steeply dipping, radially distributed zones (orange ellipses in Figure 4). The radial pattern became increasingly symmetrical around the sample throughout the rest of the experiment as these zones propagated and as micro-cracks localized along new zones (pink ellipses in Figure 4). In the heat-treated sample, strikes were dominated by the pre-existing porosity throughout deformation, although the initial localized damage zone observed at scan H (orange ellipse in Figure 5) was conjugate to the eventual fault zone seen at scan J (pink ellipse in Figure 5).

606 **3.2 Evolution of specimen and microcrack characteristics with strain**

607 *3.2.1 Stress, porosity and the number of voids*

608 Both samples had a similar stiffness early on (Figure 9a) but the heat-treated sample
609 became stiffer at 0.84% strain when the number of voids decreased slightly (Figure 9c). This is
610 consistent with compaction of the compliant thermal microcracks. The onset of localization, as
611 determined visually from the CT volumes, is evident in both samples as a yield point in the stress-
612 strain curve; at 1.37% strain and 1.24% in the untreated (Figure 4F) and heat-treated (Figure 5H)
613 samples respectively. Further yielding occurred once the damage zone propagated at 95% σ_c in
614 the heat-treated sample (Figure 5M), but only from 97% σ_c in the untreated sample (Figure 4O).

615 The heat-treated sample had lower pre-existing porosity than the untreated sample
616 ($\varphi_{0\,HT} = 0.62\varphi_{0\,UT}$) and fewer but slightly larger voids ($N_{0\,HT} = 0.54N_{0\,UT}$), with half the
617 number of voids accounting for two-thirds of the porosity seen in the untreated sample (Figure
618 9b,c). However, this observation only accounts for voids visible above the detection threshold of
619 the segmentation algorithm (a void volume of 3000-4000 μm^3 – see Section 3.3.1), and does not
620 include unresolved nano-scale thermally-induced cracks. The observed differences may be
621 accounted for by natural sample variation within these very small samples and/or some void
622 closure from thermal expansion during the heat-treatment.

623 Both samples showed a ten-fold increase in porosity, φ, over the duration of their respective
624 deformation experiment (Figure 9b), but only a two-fold increase in the total number of voids, N,
625 in the heat-treated sample, compared with a nearly three-fold increase in the untreated sample
626 (Figure 9c). This indicates that crack nucleation was more dominant in the untreated sample,
627 compared with crack growth in the heat-treated sample. The untreated sample showed no evidence
628 of compaction in the early stages of deformation and the onset of localization (Figure 4E-F) is
629 evident as a large jump in N of 600 voids at 1.37% strain, and a corresponding three-fold increase
630 in φ (Figure 9). Conversely, in the heat-treated sample a small decrease in N of approximately 50
631 voids provides evidence for some early compaction due to void closure, although this equates to
632 only a tiny proportion (0.005%) of φ_0. This was associated with the closure of some optimally
633 oriented (shallow dipping) voids prior to localization (Figure 8 – orange stereonets). The onset of
634 localization is evident as a minimum in both φ and N at 1.24% strain (Figure 5H) and both
635 variables exceeded their initial values when the optimally oriented damage zone localized (Figure
636 5K). Once localization initiated, both samples showed an overall acceleration towards failure in
637 both φ and N. However, in the untreated sample there were two occasions where the acceleration
638 was temporarily arrested. The first of these corresponded to the propagation of new localized zones
639 (Figure 4J), while the second corresponded to the change in orientation of the bridging zone
640 (described in Section 3.1). The heat-treated sample showed a slight slow-down in acceleration that
641 corresponded to the nucleation of new micro-cracks between the two ends of the eventual fault
642 (described in Section 3.1), followed by a final acceleration immediately before dynamic rupture.

643 In both samples the evolution of both φ and N with strain is best described with simple
644 power-law models (Figure 9b,c); i.e., they have the lowest $AICc$, (Tables S2 and S3 in SI). The
645 exponent is 3.1 for both variables in the untreated sample, compared with 8.8 and 7.7 for φ and N
646 respectively in the heat-treated sample, showing an acceleration towards failure that was almost
647 three times faster in the heat-treated sample than the untreated one. These exponents also show
648 that the acceleration in N accounted for all of the acceleration in φ in the untreated sample,

649 confirming that crack nucleation was the dominant damage mechanism throughout deformation,
650 whereas in the heat-treated sample, the acceleration in N did not completely account for all of the
651 acceleration in φ, confirming that crack growth played an increasingly important role closer to
652 failure.
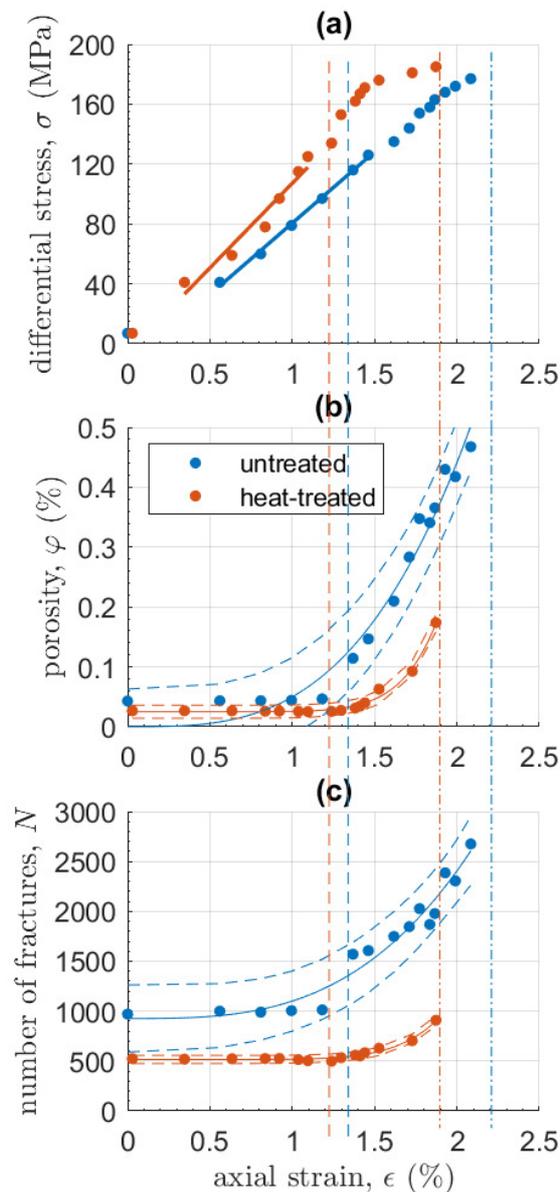

653

654 **Figure 9:** Evolution of (**a**) differential stress, σ, (**b**) porosity, φ and (**c**) the number of
655 segmented voids, N, with increasing axial strain, ϵ for the untreated sample (blue circles) and the
656 heat-treated sample (orange circles). Dash-dot lines show the strain at which each sample failed,
657 while dashed lines show the onset of damage localization as seen the μCT volumes (Figure 4 and
658 Figure 5). Solid lines in (**a**) show the region of data used to calculate the Young's moduli (9.5 and
659 11.3 GPa for the untreated and heat-treated samples respectively). Solid lines in (**b**) and (**c**) show
660 the preferred simple power-law models with 95% confidence intervals shown as dashed lines; see
661 text for exponents.

662   *3.2.2   Micro-crack geometry*

663   To establish empirically how the micro-crack geometry evolves with increasing
664   deformation, we present the variation with strain of the mean value of the major, minor and
665   medium ellipsoid radii from the population of voids in each µCT sub-volume (Figure 10a,b). We
666   also show the mean ellipsoid eigenvalue ratios, used to infer the evolution of void aspect ratio
667   (Figure 10c,d). We present two ratios: (i) the smallest to the medium eigenvalue of the covariance
668   matrix (Section 2.5.2 and Text S1b in SI), where flatter objects have smaller values, and (ii) the
669   medium to the largest eigenvalue, where more elongated objects have smaller values.

670   Corresponding mean void radii, $\bar{r}$, were about the same size in both samples. In the
671   untreated sample (Figure 10a) $\bar{r}_{major}$ and $\bar{r}_{medium}$ (blue and orange circles respectively) began to
672   increase at the onset of localization (Figure 4F). In the heat-treated sample (Figure 10b) they began
673   to increase as micro-cracks localized along the optimally oriented damage zone (Figure 5K), after
674   the onset of localization. In both samples, r_{major} were oriented approximately parallel to the strike
675   of the eventual fault plane (Figure 6c,d), with their mean values, $\bar{r}_{major}$, increasing more quickly
676   than $\bar{r}_{medium}$, showing that micro-cracks grew twice as fast along strike (i.e., perpendicular to σ_1)
677   than down dip, becoming more elongate as deformation progressed (Figure 10c). Voids in the heat-
678   treated sample were marginally flatter than those in the untreated sample, with voids in both
679   samples becoming flatter as failure approached (Figure 10d). This implies that the scaling of crack
680   growth, while scale-invariant in length, may be self-affine (variable aspect ratio) rather than self-
681   similar (constant aspect ratio). The down-dip extent ($\bar{r}_{medium}$) increased from 2.5 to 4 times the
682   crack aperture ($\bar{r}_{minor}$ – yellow circles). In the heat-treated sample, this was due to continued crack
683   growth down dip relative to a constant crack aperture (Figure 10b). However, in the untreated
684   sample, crack growth down dip stopped altogether close to failure and a small decrease in aperture
685   accounted for the voids becoming flatter (Figure 10a). Growth along strike also stopped (within
686   error), and the continued increase in the number of cracks at this stage (Figure 9c) confirms that
687   nucleation of new cracks accounted for almost all the porosity generation close to failure in this
688   sample.

689   In summary, the average growth pattern of individual micro-cracks is independent of
690   heterogeneity in the early stages of localization. The behavior changes close to failure, with
691   continued crack growth in the heat-treated sample accounting for the faster acceleration in porosity
692   than void number, while crack growth in the untreated sample was effectively halted in favor of
693   crack nucleation, which accounted for the entire acceleration in porosity and void number as failure
694   approached.
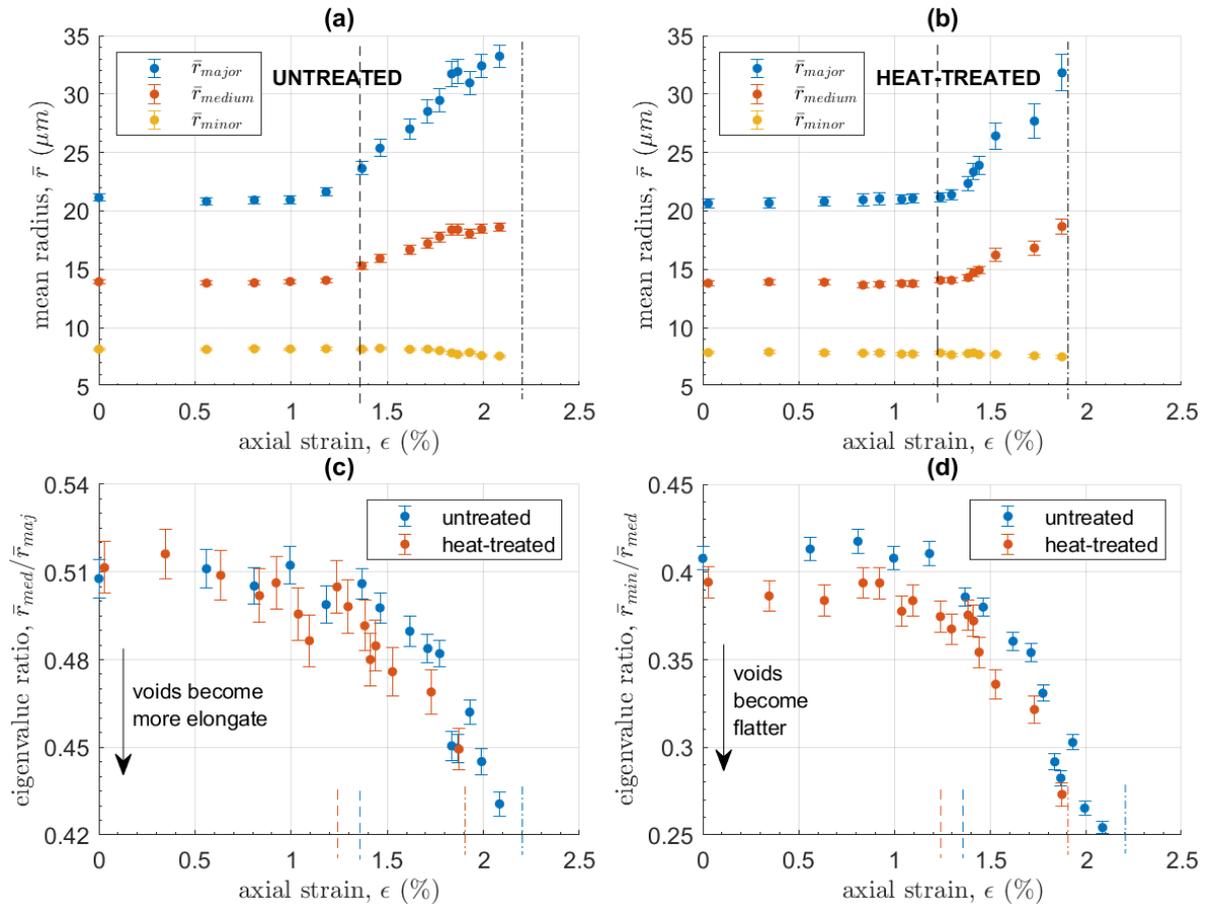

Figure 10: (**a,b**) Evolution with strain of the mean void ellipsoid radii, $\bar{r}_{major}$ (blue circles), $\bar{r}_{medium}$ (orange circles) and $\bar{r}_{minor}$ (yellow circles), for the (**a**) untreated and (**b**) heat-treated samples. (**c,d**) Evolution of mean void eigenvalue ratios (**c**) $\bar{r}_{med}/\bar{r}_{maj}$ and (**d**) $\bar{r}_{min}/\bar{r}_{med}$ with strain in the untreated (blue circles) and heat-treated (orange circles) samples. Voids become flatter or more elongate as the respective ratio → 0. Error bars show the standard error of the mean in each μCT sub-volume. Dash-dot lines show the failure strain for each sample while dashed lines show the onset of localization as seen in the μCT volumes.

704 **3.3   Evidence for phase transition style**

705   To establish the type of phase transition undergone by each sample, we present the
706 evolution to failure of the correlation length and the scaling relations as a function of both
707 differential stress σ and axial sample strain ϵ. Renard et al. (2018) argue that stress is a stronger
708 control variable than strain, but strain is usually the only directly-observable control parameter in
709 real Earth applications. We first present the scaling relationships for void volume and inter-void
710 length, and then show how the correlation length, ξ (linear dimension of the largest void) evolves
711 as a function of stress. We then analyze the evolution of ξ, β and D (the void volume and inter-
712 void length exponents respectively, defined in Section 2.5.3) as a function of strain.

713   *3.3.1   Microcrack volume and inter-crack length distributions*

714   Both samples show an approximately power-law complementary probability distribution
715 in void volume, V_i, (Figure 11a,b), with the proportion of larger voids increasing systematically
716 with respect to strain and stress. Both samples also show an approximately power-law distribution
717 in their inter-void lengths, L_i (Figure 11c,d), within a finite range, identified as $30 < L_i < 1350$
718 μm (close to half the sample diameter), with little apparent difference in the shape of the
719 distributions as stress and strain increase. We can therefore define power-law scaling exponents β
720 from the frequency-volume distributions and the correlation dimension D from the inter-void
721 length distributions.

722   Values of completeness volume, V_t (defined in Section 2.5.3), ranged from 3000 to 4000
723 μm^3, roughly equivalent to a void aperture of 14-16 μm. This is much larger than the theoretical
724 detection threshold of half the pixel size (1.3 μm) consistent with under-sampling of very narrow
725 cracks during segmentation. Void volumes in the untreated sample are best described (i.e., have
726 the lowest BIC) by the truncated Pareto distribution (TRP) at the three earliest steps of deformation
727 and then by the characteristic Pareto distribution (GR), with the transition between the two models
728 occurring at 43% σ_c, two stages before the onset of localization (Figure S2 in the SI). In contrast,
729 void volumes in the heat-treated sample are best described by the GR distribution throughout the
730 experiment.

731
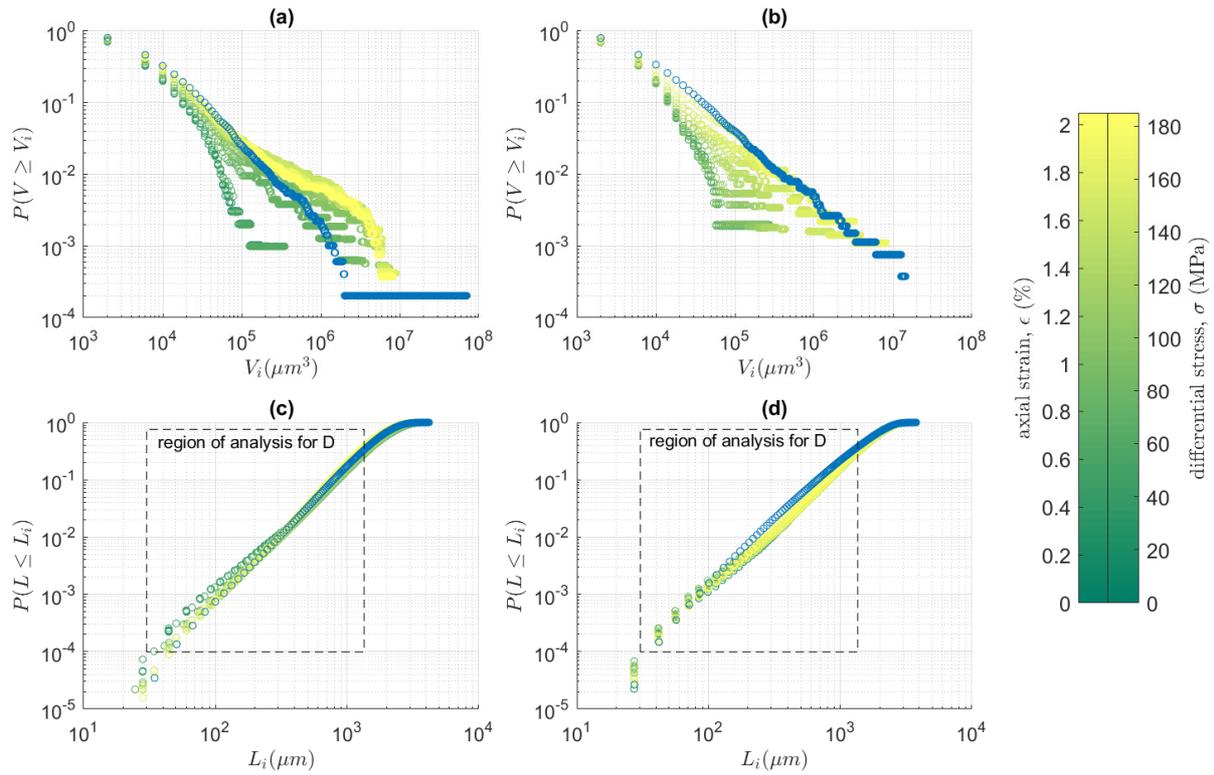

Figure 11: (**a,b**) Cumulative complementary probability distributions of void volumes, V_i, computed with a bin width of 4000 μm^3, and (**c,d**) cumulative probability distributions of inter-void lengths, L_i, computed with 256 bins, at each increment of stress and strain in the (**a,c**) untreated and (**b,d**) heat-treated samples. As described in Section 2.5.3, we obtained maximum likelihood estimates for β from the cumulative complementary V_i data (see Figure S1 in SI) using the models of Kagan (2002), and fitted the incremental L_i data using linear regression in log-log space (see Figure S3 in SI) to find D, after Turcotte (1997). Blue distributions overlaying the rest are post-failure.

740

741   *3.3.2   An inverse power-law acceleration to failure?*

742   Parameters for an inverse power-law acceleration to failure for the normalized correlation
743 length, ξ/l, were obtained for both samples (Figure 12), using data observed in segmented μCT
744 volumes between Figure 4F-O and Figure 5H-O and the method described in Section 2.5.3. While
745 an inverse power-law acceleration is commonly only distinguishable from an exponential
746 acceleration within 10% of the singularity (Bell et al., 2013b), restricting the data to this region
747 (stages L-O in the untreated sample and K-O in the heat-treated sample) would have left very few
748 data points for the analysis. In the untreated sample the exponential and inverse power-law models
749 are indistinguishable over the data range, and the predicted failure stress, σ_p, is far from the
750 observed failure stress, σ_c. The likelihood that the inverse power-law model fits the data as well
751 as the exponential model is just 3% (Table S5 in SI). Thus, it is impossible to define an accurate
752 failure point in this sample. The sample failed abruptly, long before the predicted singularity, after
753 an exponential acceleration in the correlation length. Conversely, in the heat-treated sample, σ_p is
754 accurate to within 3% of σ_c, while the asymptote of the exponential model is further from σ_c. The
755 likelihood of the exponential model fitting the data as well as the inverse power-law is 72% (Table
756 S5 in SI), which although relatively high, is not significant (>95%). These differences are
757 diagnostic of a first (abrupt) and second (continuous) order phase transition respectively (Figure
758 1), validating our hypothesis that, within the temporal resolution of our experiments, the transition
759 to failure is first-order in the untreated sample and second-order in the heat-treated sample.
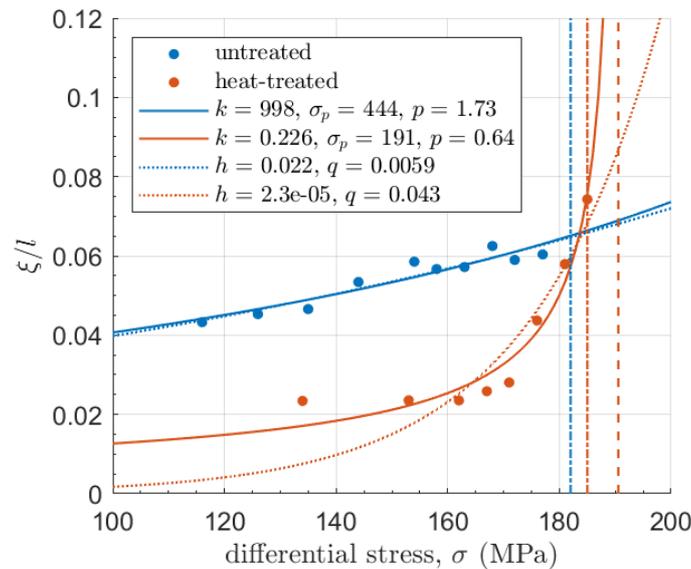

760

761   **Figure 12:** Evidence for an inverse power-law acceleration (solid lines) with respect to
762 stress in the correlation length (normalized by the length of the analyzed sub-volume): $\xi/l =$
763 $k(\sigma_p - \sigma)^{-p}$ in the heat-treated sample (orange), to a predicted failure stress, σ_p, within 3% of the
764 observed failure stress, σ_c. This compares with the same model yielding a much poorer prediction
765 in the untreated sample (blue), where $\sigma_p = 2.4\,\sigma_c$. Dotted lines correspond to the exponential
766 model, $\xi/l = h\exp(q\sigma)$, which in the heat-treated sample is less likely and in the untreated
767 sample is more likely than the inverse power-law model (the relative likelihood of each model is
768 expressed in the main text and also in Table S5 in SI, along with the $AICc$ values). The dash-dot
769 lines show σ_c for both samples and the dashed line shows σ_p for the heat-treated sample.

3.3.3 Evolution of crack population metrics with respect to strain

Both samples show a systematic increase in the correlation length ξ towards failure as a function of strain, with failure occurring when ξ increased beyond $200\,\mu m$ (Figure 13a). This limit marks the longest crack supported by the sample volume without a runaway instability developing, and falls just short of the mean grain size (i.e., the length between grain boundaries) of the groundmass ($250\,\mu m$ – see Section 2.1). This implies that the sample breaks when whole grains break. The nature of the increase in $\xi(\epsilon)$ in the untreated sample (blue) was exponential (i.e., had the lowest $AICc$ – see Table S4 in SI) up to a finite ξ that fluctuated around $200\,\mu m$ before failure. Conversely, in the heat-treated sample (orange) $\xi(\epsilon)$ preferred a simple power-law acceleration (Figure S4 and Table S4 in SI) to failure, failing when $\xi > 200\,\mu m$. The exponent (6.9) is the same (within error) as the exponents for the evolution of φ and N with strain (Section 3.2.1; Tables S2-S4 in the SI), independently confirming that in this sample crack growth played an increasingly important role closer to failure. The power-law acceleration emerges only once fractures began to localize along the optimally oriented damage zone (at 90% σ_c and $\xi > \xi_0$), representing a strong self-organization in the crack network over all distances to concentrate on the damage zone that controls the eventual fault plane.

The two samples had different initial exponents β for their volume distributions (Figure 13b). In the untreated sample (blue) β rose sharply to a peak at the transition from the TRP to the GR model. This shows that, at this point, the largest cracks in the taper were growing or opening, while simultaneously many more small cracks were becoming active above the segmentation detection threshold. The number of voids and the porosity were constant in this phase, implying other voids were simultaneously closing in compaction (Figure 9b,c). This trade-off is consistent with independent observations from acoustic emissions (Graham et al., 2010) and models (e.g. Brantut et al., 2012; 2014) of the competition between compaction and dilatancy during the quasi-elastic region of the stress-strain curve (Figure 9a). Beyond this peak, β decreased smoothly to the first of two local minima once the additional radial zones had localized (Figure 4K). This indicates instability in the sample-related crack nucleation (Figure 9c and Figure 10a) and might be considered a precursor to failure, albeit without evidence of quasi-static damage zone propagation within the temporal resolution of the method. Conversely, in the heat-treated sample (orange) β decreased throughout, reflecting an increase in the relative proportion of larger micro-cracks. This change occurred gradually at first and then more sharply once cracks localized along the optimally oriented shear zone, similar to that observed in numerical simulations (Kun et al., 2013) and as inferred from AE magnitude distributions (Sammonds et al., 1992) in dry porous media. The sharp drop in β is a clear precursor to failure, corresponding to propagation of the shear zone through the sample (Figure 5M-O). This supports our hypothesis that the heat-treated sample exhibits the clear precursors associated with a second-order phase transition.

The evolution of the two-point correlation (fractal) dimension D was very different between the two samples (Figure 13c). Initially there was a greater degree of clustering in the untreated sample (blue) than the heat-treated one (orange). In both samples D shows a minimum in the two time windows before the onset of localization, demonstrating the sensitivity of D to localization (see also Bonnet et al., 2001). The degree of clustering at this point, reflected in the value of D, was very similar between the two samples. From this point on, D in the untreated sample increased significantly as micro-cracks became more distributed (less clustered) along the radial zones. Conversely, in the heat-treated sample D shows increased clustering that was sustained throughout localization. It recovered (implying decreased clustering) to a relatively

815   constant value as the optimally oriented shear zone propagated stably through the sample before
816   accelerating at the point of failure as the shear zone spanned the sample. Thus, D highlights clear
817   differences in the spatial distribution of the micro-crack network between the increasingly
818   distributed damage zones in the untreated sample and localization of an asymmetric shear fault in
819   the heat-treated one. The increasingly distributed nature of crack damage in the untreated sample
820   gives no indication of potential failure, while increased clustering due to localization in the heat-
821   treated sample is a clear and early precursor to failure associated with the development of a damage
822   zone optimally oriented to encourage system-sized shear failure. While both samples show
823   precursory changes, only the heat-treated sample has precursors capable of accurately forecasting
824   the point of system sized catastrophic failure.

825
826
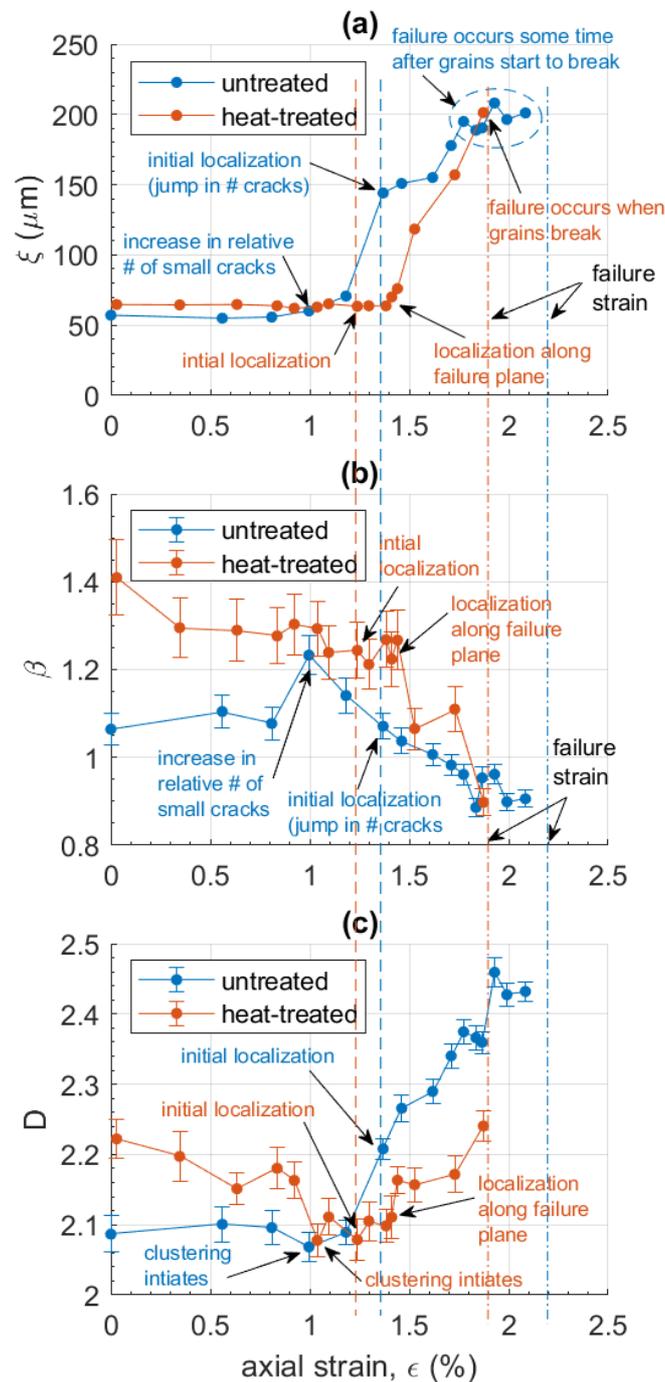

Figure 13: Evolution with strain for (**a**) correlation length ξ, (**b**) microcrack volume exponent β, and (**c**) fractal dimension D, for the untreated (blue) and heat-treated (orange) samples. Error bars show (**b**) the standard error ($\beta/\sqrt{N}$) of the maximum likelihood estimate of β, where N is the number of cracks, and (**c**) the 95% confidence intervals of the linear regression fit for D. Dash-dot lines show the strain at which each sample failed, while dashed lines show the onset of localization as seen in the μCT volumes.

834 **4 Discussion**

835   The results presented above reveal key aspects of the evolving nature of compressive
836 failure of brittle rocks through the accumulation of micro-cracks that spontaneously organize
837 themselves along localized damage zones. Our synchrotron x-ray micro-tomography (μCT)
838 observations of *in-situ* compressive rock deformation reveal the underlying processes – in
839 particular the nature of the phase transition between intact and failed states in materials with
840 different degrees of starting heterogeneity. Both our post-failure samples contained a localized
841 shear fault, but the preceding accumulation of micro-cracks was very different between the
842 samples, especially in their spatial distribution and their growth characteristics close to failure. We
843 confirm our hypothesis that, in terms of stress and within the time-resolution of our experiments,
844 the transition to failure is abrupt and unpredictable (first-order) in the homogeneous sample, but
845 continuous and predictable (second-order) in the heterogeneous sample.

846   **4.1   Microcrack network evolution**

847   Prior to failure, our initially crack-free, and therefore more homogeneous, sample
848 accumulated damage in a spalling pattern of localized zones distributed radially around the sample
849 with no preferred strike direction. This damage pattern was completely overprinted during failure,
850 highlighting the drawback of analyzing failed samples retrospectively to gain insights into pre-
851 failure damage accumulation. Pre-failure behavior in this sample resembles strain localization
852 observed from *in-situ* μCT images of deforming mono-minerallic, fine-grained and uniformly
853 graded (i.e., structurally homogeneous) sand specimens (Desrues et al., 1996). The macroscopic
854 fault localized abruptly at >97% of peak (failure) stress, σ_c, as microcracks transitioned from being
855 broadly distributed throughout the sample (albeit along several radially oriented zones) to being
856 organized along an emerging shear zone.

857   In contrast, our pre-cracked, and therefore more heterogeneous, sample accumulated
858 damage around, and subsequently failed along, a localized shear zone. This behavior resembles
859 the observations of Lockner et al. (1991; 1992) who showed progressive localization of AE along
860 a shear zone in deforming Westerly granite samples from peak stress onwards. However, in our
861 experiment the shear zone localized earlier, at 90% of σ_c, with a subsequent period of stable crack
862 nucleation and growth along the damage zone during strain hardening prior to dynamic rupture at
863 peak stress. This behavior resembles fault nucleation and propagation from AE in Berea (Lockner
864 et al., 1992) and Clashach (Liakopoulou-Morris, et al. 1994; Lennart-Sassinek et al., 2014)
865 sandstone samples (arguably more heterogeneous than granite samples in terms of their porosity),
866 where a diffuse damage zone appeared and gradually localized around an incipient fault plane prior
867 to σ_c.

868   Our results show that heterogeneity exerts a strong control on the evolution of crack
869 network anisotropy, with homogeneity acting to stabilize the system prior to dynamic failure,
870 generating more complex patterns of strain localization with more isotropic global characteristics,
871 as suggested by Desrues et al., (1996). Under axi-symmetric triaxial loading conditions, sample
872 homogeneity is a constraint that favors a transversely isotropic spalling pattern until very close to
873 peak stress, whereas the presence of heterogeneity acts to amplify the pre-existing anisotropy with
874 the formation of a shear fault. Radial spalling patterns are rarely observed in studies of AE,
875 potentially due to limits on their location accuracy, where microcracks occurring along several
876 radially distributed, but localized, damage zones might give the impression of being distributed
877 throughout the sample.

878   In both of our samples, damage accumulated via the nucleation and sub-critical growth of
879 micro-cracks along localized damage zones. En-echelon and wing-crack arrays formed at different
880 stages in the deformation process in each sample (at initial localization in the untreated sample but
881 only once the optimally oriented shear zone localized in the heat-treated sample), and formed at
882 the same degree of strain (Figure 4F and Figure 5L), implying a degree of strain control. The main
883 direction of individual micro-crack growth in the localized zones was along strike rather than down
884 dip (Figure 10a,b,c). Models of damage accumulation under tri-axial compression are usually
885 based on AE locations and microstructural observations of post-failure samples, from which it is
886 difficult to quantify the relative proportion of progressive, pre-failure axial to radial micro-crack
887 growth. Along-strike growth is consistent with our conventional tri-axial compressional stress
888 configuration ($\sigma_1 > \sigma_2 = \sigma_3$), in which it is energetically more favorable for tensile micro-cracks
889 to open radially against the axes of minimum principal stress and close against the axis of
890 maximum principal stress. Down-dip fault propagation occurred instead by the nucleation, growth
891 and then linkage of an increasing number of small, tensile en-echelon and wing cracks forming at
892 the fault tip (Figure 6a,b, Figure 7 and Figure 9c). This is consistent with previous experimental
893 and modelling work (e.g., Tapponnier and Brace, 1976; Kranz, 1979; Nemat-Nasser and Horii,
894 1982; Horii and Nemat-Nasser, 1985; 1986; Sammis and Ashby, 1986; Ashby and Hallam, 1986;
895 Nemat-Nasser and Obata, 1988; Rundle and Klein, 1989; Ashby and Sammis, 1990; Reches and
896 Lockner, 1994; Potyondy and Cundall, 2004; Cho et al., 2007) and recent *in-situ* observations of
897 damage accumulation in strong rocks (Renard et al., 2017; 2018).

898   We observed significant anisotropy of void strike in the pre-existing porosity in both
899 samples (Figure 6c,d), despite visual inspection of thin sections and compressional wave velocities
900 of the same rock type showing only 1% anisotropy in bench-top tests on the original material
901 (Meredith et al., 2005; Meredith, pers comm.). This indicates that a small velocity anisotropy
902 represents substantial void anisotropy. The pre-existing void anisotropy is more pronounced in the
903 heat-treated sample than in the untreated sample, possibly due to thermal expansion during the
904 heat-treatment acting to close the isolated, mainly round voids in the feldspar micro-phenocrysts
905 (Meredith et al., 2012). This may also account for the otherwise counter-intuitive smaller overall
906 porosity in the heat-treated sample compared with the untreated one. The application of confining
907 pressure may also have contributed to the porosity difference by acting to close the thermally-
908 induced cracks in the heat-treated sample more effectively than the stiffer pores in the untreated
909 sample. In the heterogeneous sample, the preferred strike of the pre-existing porosity corresponds
910 almost exactly to the strike of the emerging fault plane (Figure 6d). There was also significant
911 amplification of the pre-existing anisotropy of the rock fabric (from 33% to 96% just before failure;
912 Table S1 in SI). This was not the case in the homogeneous sample, where the degree of anisotropy
913 remained approximately constant throughout the lead-up to failure (Table S1 in SI), consistent
914 with the lack of an overall preferred strike in the pre-failure localized zones in this sample.

915   The results in the previous paragraph prove that the initial microstructure, specifically the
916 orientation and anisotropy of pre-existing porosity dictated the geometry and location of the future
917 (post-failure) fault, particularly in the heat-treated sample. We speculate that this happens via a
918 modification of the local stress field with respect to the principal stress axes. In true tri-axial
919 configurations ($\sigma_1 > \sigma_2 > \sigma_3$), shear wave velocity anisotropy measurements have shown that
920 micro-cracks in general propagate parallel to σ_2 as they open parallel to σ_3 (Crawford et al., 1995),
921 while polymodal faulting is also often seen (Healy et al., 2015). Thus, although the global stress
922 configuration is axi-symmetric in our case, both heterogeneity and void anisotropy in the
923 microstructure appear to cause the local development of truly tri-axial stresses such that a particular

924 strike is preferred. One possible mechanism for this may be stress rotation around microstructural
925 discontinuities (Faulkner et al., 2006), possibly reflected in our experiments in the rotation of the
926 void ellipsoids with respect to the principal stress axes (Figure 6c,d). In this case, the pre-existing
927 network of anisotropic micro-cracks with a preferred orientation would have generated an
928 emergent, locally dominant true-triaxial stress field within the body of our heterogeneous sample,
929 even though the confining pressure was isotropic around the vertical (σ_1) axis. Conversely, in our
930 homogeneous sample, some complex interplay between local true tri-axial stresses and global axi-
931 symmetry would be required to generate several radially distributed damage zones simultaneously.
932 We speculate that the global axi-symmetry initially counteracts the rotation of internal stresses in
933 this sample, acting to prevent an increase in crack anisotropy and thereby increasing the uniformity
934 of the strike distribution as the experiment progresses. Thus, the relationship between the evolving
935 anisotropy of the micro-cracks and their preferred orientation is likely to be a controlling factor on
936 the geometry and location of an asymmetric shear fault, on the timing of the formation of this fault
937 and on whether pre-failure damage is localized along this fault or not.

938 In both our samples, the majority of cracks dip steeply within ±15° of the loading direction,
939 although a few dip less steeply between 15 and 30° (Figure 6a,b). This is consistent with the results
940 of post-failure sample analysis in early experimental work (Brace et al. 1966; Hallbauer et al. 1973;
941 Lajtai 1974). The macroscopic fault in our homogeneous sample dips at a similar angle to the pre-
942 failure micro-cracks, whereas in our heterogeneous sample it dips less steeply post-failure than it
943 does at peak stress. Although the effective pressure was relatively low (15 MPa), which may
944 promote axial failure over shear, it was consistent across the two experiments. This implies that
945 the differences in fault dip result from an intrinsic microstructural response, whereby the emergent
946 internal friction coefficient decreases during failure in the heterogeneous sample but remains
947 constant in the homogeneous sample, consistent with DEM models (Kun et al., 2018) that show a
948 decreasing coefficient of internal friction with increasing heterogeneity. In both samples, the dip
949 angle increases during quasi-static damage accumulation, increasing earlier in the homogeneous
950 case (during initial localization) than the heterogeneous case (only during localization around the
951 optimally oriented shear zone). In the homogeneous case, the steep dip of the nucleating cracks
952 (Figure 6a and Figure 7a) and the eventual fault plane (10°; Figure 6a) indicates that the internal
953 friction coefficient in this sample is sufficiently high to inhibit micro-crack damage by shear
954 mechanisms until immediately before dynamic failure. In the heterogeneous case, the dip, and
955 therefore the internal friction coefficient, increases only during propagation of the shear zone and
956 is particularly pronounced immediately before failure (Figure 6b), while the eventual fault plane
957 dips less steeply (30°; Figure 6b). This indicates that early crack nucleation and failure itself both
958 involve shear mechanisms, but shear zone propagation is governed primarily by tensile
959 mechanisms, i.e., the accumulation of en-echelon tensile cracks (Figure 7b), with a corresponding
960 increase in the internal friction coefficient. For this reason we have referred to a 'damage zone'
961 prior to failure and a 'fault plane' afterwards.

962 In our homogeneous sample, increased clustering (Figure 13c; blue circles) occurred at
963 43% σ_c with the onset of localization at 64%. This agrees with observations and models of cracks
964 initiating earlier than the theoretical shear-sliding threshold for more homogeneous low porosity,
965 crystalline rocks (70% σ_c; Hallbauer et al., 1973; Nicksiar and Martin, 2013; 2014). The
966 implication is that our more homogeneous sample is weakest in tension and, once a sufficient
967 number of tensile cracks form, a macroscopic shear fracture will naturally develop. We therefore
968 conclude that damage in this sample most likely initiated via the nucleation of pore-emanating
969 (Sammis and Ashby, 1986; Ashby and Sammis, 1990) or force-chain controlled (Potyondy and

970 Cundall, 2004; Cho et al., 2007) tensile micro-cracks due to the re-distribution of stress around
971 equant compressing pores and grains. Conversely, increased clustering in our heterogeneous
972 sample (Figure 13c; orange circles) occurred at 62% σ_c with the onset of localization at 72%. This
973 is later than the theoretical shear-sliding threshold for heterogeneous rocks (60% σ_c; Hallbauer et
974 al., 1973; Nicksiar and Martin, 2013; 2014). The implication here is that our more heterogeneous
975 sample is weaker in shear than in tension since shear sliding along preferentially oriented, pre-
976 existing cracks occurred before tensile cracking. We therefore conclude that damage in this sample
977 most likely initiated via the development of tensile 'wing-cracks' (Nemat-Nasser and Hori, 1982;
978 Horii and Nemat-Nasser, 1985; 1986; Ashby and Hallam, 1986; Nemat-Nasser and Obata, 1988;
979 Ashby and Sammis, 1990) at the tips of pre-existing defects due to shear-sliding along those
980 defects. Unfortunately, such shear sliding would not be visible in our images without significant
981 dilatancy during slip.

982 In summary, our experimental data confirm that the initial heterogeneity within a rock
983 sample is a key control over how cracks, pores and grain boundaries interact locally with the
984 applied stress field, and imply that the microstructure transitions from being weakest in tension to
985 being weakest in shear as heterogeneity increases.

986 **4.2   Scaling, phase transition style and predictability of failure time**

987 Micro-crack volume and inter-crack length distributions follow power-laws throughout the
988 cycle of deformation and failure in both samples, characteristic of the scale-invariant (fractal)
989 nature of natural fault networks (Main et al., 1990; Bonnet et al., 2001) and consistent with the
990 power-law microcrack volume distributions observed by Renard et al. (2017; 2018). The transition
991 from the TRP to the GR model for the micro-crack volume distributions (Figure S2 in SI) in the
992 homogeneous sample emulates changes in the organization of earthquake size distributions
993 following the occurrence of extreme or very large earthquakes (Bell et al., 2013a). Close to failure
994 the void volume distribution shows a bump at large volumes, indicative of a supercritical state
995 with an elevated probability of occurrence of large events (Main, 1996), sometimes known as
996 'dragon kings' (Sornette, 2009). We have demonstrated that the parameters of these distributions
997 are more sensitive to heterogeneity than porosity alone, consistent with the findings of Vasseur et
998 al. (2017) and Kun et al. (2018). In combination with µCT observations of fault formation, the
999 evolution of these parameters provides a microstructural explanation for the variation in the
1000 systematic prediction error for the failure time based on acoustic emissions (Vasseur et al. 2015).

1001 However, the systematic change in the mean void aspect ratios during crack growth may
1002 indicate that the scaling of crack growth is self-affine (i.e., exhibits scale-invariance in length with
1003 different exponents for individual growth axes, leading to a variable aspect ratio) rather than self-
1004 similar (the same scaling exponent for all growth axes, with a constant aspect ratio). This is
1005 consistent with observations of fracture surface geometries in rocks (Schmittbuhl et al., 1995) and
1006 other materials (Mandlebrot et al., 1984; Bouchaud et al., 1990; Russ, 1994; Schmittbuhl and
1007 Maloy, 1997; see also Bouchaud, 1997 for a review), which are well-described by self-affine
1008 fractals. These studies have shown that scaling along the aperture axis is systematically smaller
1009 than along the mean crack plane, with the systematic (Hurst) exponent defining the fracture
1010 roughness (Bouchaud, 1997; Weiss, 2001). Our observation that almost no growth at all occurs
1011 along the aperture axis supports the conjecture that the aperture direction is not physically
1012 equivalent to the mean crack plane (Schmittbuhl et al., 1995). Our results indicate that scaling
1013 along the strike and dip axes may also systematically differ from each other. This contradicts the

1014   notion of strict self-similarity in the mean crack plane (Schmittbuhl et al., 1995), and implies that
1015   the strike and dip directions are not physically equivalent either. Further work is required to
1016   quantify the scaling anisotropy for crack growth in our experiments and to test these hypotheses.
1017   Since crack surfaces in crystalline materials require heterogeneities, such as grain boundaries and
1018   dislocations that pin the propagating crack front, in order to develop self-affine roughness
1019   (Schmittbuhl and Maloy, 1997; Bouchaud, 1997; Weiss, 2001), we expect that scaling exponents
1020   for the heterogeneous sample may be more anisotropic than for the homogeneous sample.

1021   In the heterogeneous (heat-treated) case, we find evidence for a continuous (second-order)
1022   phase transition in the inverse power-law acceleration to failure of ξ with respect to stress (Figure
1023   12; solid orange line), with failure occurring near the asymptote, together with clear precursors in
1024 β and D. The rapid decrease in β corresponds to the formation of a localized damage zone
1025   optimally oriented for macroscopic shear failure, occurring when the microcrack network self-
1026   organizes. This provides a clear precursor to sample failure related to a distinct physical process,
1027   i.e. the emergent inverse power-law acceleration in ξ. The asymptote defines a predictable failure
1028   time defined by a smooth transition to an infinite ξ at the sample-scale (Figure 1; orange line). The
1029   early and sustained decrease in D in 3D is a key precursory indicator of localization, while its
1030   recovery is associated with shear zone propagation in 2D, as anticipated by the model of Main
1031   (1992). This provides another clear precursor to failure. Such behavior agrees with statistical
1032   physics models of rupture as a critical, second-order phenomenon (Girard et al., 2010; Kun et al.,
1033   2013). Thus, taken together, these variables show that damage localization along a zone optimally
1034   orientated for macroscopic shear failure is the physical process that defines whether the phase
1035   transition from an intact to a failed state is second-order, and therefore predictable, with reliable
1036   precursors to failure.

1037   In the homogeneous (untreated) case, we find evidence for an abrupt or discontinuous
1038   (first-order) phase transition, with an unsuccessful forecast of the failure stress, and a preference
1039   for an exponential model for the evolution of the correlation length, ξ, with respect to stress.
1040   Furthermore, there is very little evidence for reliable precursors in either the micro-crack volume
1041   exponent, β, or the two-point fractal dimension, D, and the bump in the void size distribution at
1042   large volumes is reminiscent of a first-order phase transition (Lominitz-Adler et al., 1992; Ceva
1043   and Perazzo, 1993). Approaching failure we see small fluctuations in β, ξ and D that may indicate
1044   impending failure as they are associated with formation of the additional damage zones and
1045   subsequent microstructural instability due to crack nucleation close to failure. However, using
1046   these parameters as precursors may lead to false alarms since they are not associated with the
1047   eventual fault plane. The exponential increase in ξ (implying that local correlations dominate) is
1048   unusual and generally associated with the critical regime during phase transitions across surfaces
1049   (Kosterlitz and Thouless, 1973; Kosterlitz, 1974), such as during large-scale faceting at the
1050   surfaces of growing crystals (Nozières, 1992). Its stabilization to a finite value shortly followed by
1051   abrupt failure is characteristic of a first order phase transition (Figure 1; green line). In numerical
1052   models of fault growth, an exponential distribution of fault lengths is associated with crack
1053   nucleation, whereas a power-law distribution emerges with nucleation plus crack growth and
1054   coalescence (Cowie et al., 1995). Hence, the origin of this response in our rock volume may be
1055   explained by our observation that crack nucleation is the dominant damage process in the
1056   homogeneous sample while crack growth becomes increasingly important closer to failure in the
1057   heterogeneous sample (Section 3.2.1). This behavior corresponds to the existence of a metastable
1058   state of crack nucleation at a system-sized ξ during a first-order transition, when the system is

1059 vulnerable to the influence of sufficiently large perturbations (subcritical bifurcation) (Sornette,
1060 2006). This vulnerability and the resulting discontinuity may be the reason for an unpredictable
1061 failure time (Vasseur et al., 2015).

1062 An estimate for the correlation length exponent (1.15) for Carrara marble (Kandula et al.,
1063 2019) falls almost exactly halfway between the exponents for Ailsa Craig microgranite found here
1064 (0.65 for the heterogeneous sample and 1.75 for the homogeneous sample). However, the Carrara
1065 marble exponent was estimated by assuming the failure stress *a priori*, so it is not directly
1066 comparable with our results. It is therefore not possible to confirm whether an inverse power-law
1067 would successfully forecast the failure stress in real time and/or whether a different model would
1068 be more likely. Nevertheless, the nature of Carrara marble may place it halfway between our two
1069 end members. It is chemically pure, composed of 99% annealed calcite crystals (Alber and
1070 Hauptfleisch, 1999), with a homogeneous microstructure (Oesterling, 2004), a very low
1071 permeability (10^{-19} m^2) and only 0.2-0.5% connected porosity (Zhang, 1994; Alber and
1072 Hauptfleisch, 1999; Bandini et al., 2012; Cartwright-Taylor et al., 2015). However, studies have
1073 shown the presence of micro-discontinuities within grains, including twin lamellae (Ramez and
1074 Murrell, 1964; Bandini et al., 2012; Cartwright-Taylor et al., 2015) and a high density of
1075 dislocations (Fredrich et al., 1989), while its isotropic texture consists of both well-locked
1076 (xenoblastic) and more mobile (granoblastic) grain boundaries (Bandini et al., 2012; Cartwright-
1077 Taylor et al., 2015). These factors indicate a complex history of both static and dynamic
1078 recrystallization (Molli and Heilbronner, 1999; Oesterling, 2004) and introduce a degree of
1079 heterogeneity that may be intermediate between our two samples.

1080 In both samples, the critical value of ξ is 200 μm, marking the longest crack supported by
1081 the sample volume without a runaway instability developing. Significantly, this falls just short of
1082 the mean grain size of the groundmass (250 μm). That is, catastrophic failure occurs when whole
1083 grains break. This confirms the findings of Vasseur et al. (2017) from acoustic emissions (AE)
1084 data that the grain size (inter-particle distance) is a better metric for the characteristic void
1085 dimension at failure than the distance between pores (inter-void distance).

1086 Our observations highlight the strong dependence of the degree of predictability on
1087 material properties that may be unknown in a field application, as well as the importance of
1088 analyzing several independent parameters for identifying the type of phase transition and
1089 predicting the point of failure (Lei and Satoh, 2007). They may also explain why, when looking at
1090 long time-series of field-scale seismicity or deformation, clear and reliable precursors to failure
1091 are detected only in some cases, and preferentially in application to forecasting of landslides and
1092 volcanic eruptions. In other cases, notably in forecasting of individual large earthquakes,
1093 fluctuations related to instability may be present but may not be statistically significant enough to
1094 be detectable as precursors. In both samples, *D* shows increased clustering earlier than localization
1095 is visually apparent in the μCT images, and therefore may provide useful information about the
1096 impending onset of damage localization for a variety of applications and settings. Finally, the
1097 relatively high strain rates analyzed here may not be representative of the evolution of precursors
1098 at lower strain rates. For example Ojala et al. (2004) showed that the acceleration to failure in AE
1099 rate asymptotically approaches the behaviour expected of a single Griffith crack (Figure 1) as
1100 strain rate is decreased in laboratory compression tests on porous sandstones. Nevertheless, we
1101 have confirmed that heterogeneity plays a significant role in determining the style of evolution of
1102 the population of micro-cracks, and hence the predictability of the system-scale failure time.

4.3 Suggestions for future work

This discussion has highlighted some outstanding research questions to be addressed in future work. The most notable of these are as follows: (i) Why do previously obtained degrees of anisotropy inferred from acoustic measurement differ markedly from our newly obtained structural ones? (ii) How does crack growth scale (in terms of the ellipsoid radii), and is it self-affine? (iii) Does the predominant local failure mechanism change from tensile to shear as system-sized failure approaches, as seen in the AE data of Graham et al. (2010)? (iv) Does this transition occur earlier in more heterogeneous materials? Given tensile fractures are easier to see in imaging void space, the latter two questions would benefit from digital volume correlation techniques that are the subject of ongoing work, and can detect local changes in shear and volumetric strain.

5 Conclusions

Our *in-situ* time-resolved x-ray µCT images of very small samples of deforming granite show that the heterogeneity of the starting material exerts a strong control on the evolution of the statistical properties of crack size and spatial distribution during fracture network evolution. The accumulating micro-cracks have power-law frequency-volume and inter-crack length distributions over a finite scaling range, irrespective of the degree of starting heterogeneity, with well-determined scaling exponents β (the size exponent) and D (the correlation dimension). The inferred correlation length ξ increases exponentially with respect to stress in the homogeneous case, with sudden-onset, unpredictable failure, analogous to the behavior expected for a first-order (discontinuous) phase transition. In contrast, the heterogeneous sample shows an inverse power-law acceleration to a predictable failure point at the asymptote, diagnostic of a second-order (continuous) phase transition (Equation 1 and Figure 1). The second-order transition is linked to the distinct physical process of quasi-static, asymmetric accumulation of damage within an optimally-oriented zone increasingly localized around the eventual fault plane, with associated reliable precursors to failure in the evolution of β and D. The correlation dimension is a key early indicator of localization on such a shear zone for the heterogeneous sample. This is not observed within the time resolution of our observations for the homogeneous sample, where the precursory damage takes the form of more radially isotropic zones of spalling, and shear localization must occur very close to the point of dynamic failure itself to explain the post-failure observation of a shear fault.

Crack nucleation dominates the frequency-size statistics in the homogeneous case and crack growth in the heterogeneous case. In both cases, the transition to localized damage occurs by a combination of nucleation and growth. The timing of the onset of crack coalescence defines the order of the phase transition, and hence the predictability of the failure time. Nevertheless, catastrophic failure occurs in both cases as the correlation length approaches the grain size, which in turn controls the failure of local bridges between aligned en-echelon and wing-cracks in the shear damage zone in the heterogeneous sample. The initial rock microstructure, specifically the anisotropy of pre-existing porosity, dictates the geometry and orientation of the emergent fault plane, independent of starting heterogeneity. This reflects the strong control of starting microstructure on the rock's internal stress state, despite the axi-symmetric external loading conditions and the very low anisotropy (1%) inferred from acoustic velocity measurement.
