**Key Points:**

- We investigate the evolution of fault strength during realistic earthquake slip history
- The high velocity strength of carbonate built faults is compatible with flash heating at short timescales and viscous creep rheology at larger timescales.
- We document limited elastodynamic compatibility between measured fault strength and imposed slip history

**Abstract**

Theoretical studies predict that during earthquake rupture faults slide at non-constant slip velocity, however it is not clear which source time functions are compatible with the high velocity rheology of earthquake faults. Here we present results from high velocity friction experiments with non-constant velocity history, employing a well-known seismic source solution compatible with earthquake source kinematics. The evolution of friction in experiments shows a strong dependence on the applied slip history, and parameters relevant to the energetics of faulting scale with the impulsiveness of the applied slip function. When comparing constitutive models of strength against our experimental results we demonstrate that the evolution of fault strength is directly controlled by the temperature evolution on and off the fault. Flash heating accurately predicts weakening behaviour at short timescales, but at larger timescales strength is better predicted by a viscous creep rheology. We use a steady-state slip pulse to test the compatibility of our strength measurements at imposed slip rate history with the stress predicted from elastodynamic equilibrium. Whilst some compatibility is observed, the strength evolution indicates that slip acceleration and deceleration might be more rapid than that imposed in our experiments.

**1 Introduction**

During earthquakes, faults weaken abruptly, and slip accelerates to velocities of the order of several metres per second (Kanamori & Brodsky, 2004; Madariaga, 2015). The exact stress and slip evolution on faults is rarely well constrained by seismological observations, which can generally only provide estimates of integrated quantities, such as average stress drop and slip,

36   breakdown work and radiated energy  (Abercrombie & Rice, 2005; Guatteri & Spudich, 2000;

37   Kanamori & Rivera, 2006).

38

39   Fault slip can be quite complex during earthquakes, with highly variable velocity history. Models

40   and experimental observations based on fracture mechanics exhibit the common feature of a a

41   rapid acceleration to a peak velocity, corresponding to the passage of the rupture tip, after which

42   slip rate decays to zero (see theoretical overview in Scholz, 2002, Section 4.2; early laboratory

43   work by Okubo & Dieterich, 1981; Ohnaka et al., 1986, and more recent work by Rubino et al.,

44   2017; Berman et al., 2020, among many others). Kinematic source models inverted from

45   seismological data are often nonunique and require significant smoothing due to the relatively

46   low frequency data used; specific choices have to be made for the general functional form of the

47   slip history for fault patches, but the corresponding dynamic stress evolution (and associated

48   derived quantities, e.g., fracture energy) strongly depends on such model choices (Guatteri &

49   Spudich, 2000; Tinti et al., 2005). It remains unclear what source-time function would best

50   correspond to the actual traction evolution along the fault. Tinti et al. (2005) used theoretical

51   considerations to develop a source-time function that is compatible with elastodynamics, but it is

52   not guaranteed that such theoretical slip function leads to traction evolution that is compatible

53   with the rheology of the fault. Attempts have been made to verify this compatibility by

54   comparing high velocity fault rheology obtained in laboratory experiments with earthquake

55   source parameters estimated from strong motion seismograms, with limited success (Chang et

56   al., 2012; Fukuyama & Mizoguchi, 2010).

57

58 In nature, there is a feedback between the slip rate on the fault (associated with a given stress

59 state through elastodynamic equilibrium) and the shear strength of the fault zone materials. A

60 substantial body of work has shown that fault strength is dramatically lower at rapid deformation

61 rates in comparison to that during slow interseismic deformation (Faulkner et al., 2011; Goldsby

62 & Tullis, 2011; Han et al., 2007; Brantut et al., 2008; Hirose & Shimamoto, 2005; Di Toro et al.,

63 2011). The low strength observed during rapid deformation in the laboratory can explain the

64 propagation of ruptures in numerical models (Noda et al., 2009; Noda & Lapusta, 2013), and is

65 quantitatively consistent with the low heat flow and shear heating estimated from borehole

66 measurements after the 2011 Tohoku-oki earthquake (Fulton et al., 2013; Ujie et al., 2013). High

67 velocity friction experiments have shown that sliding velocity exerts a first order control in

68 governing the strength of faults (Goldsby & Tullis, 2011; Han et al., 2007; Di Toro et al., 2004,

69 2011; Tsutsumi & Shimamoto, 1997). Several physical models have been proposed to explain

70 this weakening. Nielsen et al. (2008, 2010) developed a model of frictional melting in basic

71 igneous rocks which showed good agreement with the experimental data of Hirose & Shimamoto

72 (2005). The flash heating model (FH), based on frictional heating at microscale contacting

73 asperities (Rice, 2006; Beeler et al., 2008), was successful in explaining experimental

74 observations in crystalline felsic rocks in the absence of bulk frictional melting (Goldsby and

75 Tullis, 2011) . More recently in carbonate rocks, grain size sensitive creep has been proposed to

76 explain the weakening behaviour due to the presence of nanometric grains which facilitate rapid

77 diffusive mass transfer (Demurtas et al., 2019; De Paola et al., 2015; Pozzi et al., 2018).

78

79 Although velocity exerts a direct control on fault strength, a number of studies have also

80 demonstrated the important role of fault slip history in determining strength evolution: In

81 particular, hysteresis in the frictional strength has been systematically observed between
82   acceleration and deceleration phases of experiments, suggesting a change in the physical state of

83   the fault during experiments (e.g., Goldsby & Tullis, 2011; Proctor et al., 2014; Sone &

84   Shimamoto, 2009). A number of authors have shown that this difference  can be accounted for

85   by considering the temperature rise of the fault as a state variable in FH models (Proctor et al.,

86   2014). By controlling the thermal evolution of gouge material during high velocity friction tests

87   Yao et al. (2016) demonstrated the key role of temperature in high velocity weakening

88   mechanisms. In parallel, experimental data and modelling by Passelègue et al. (2014) showed

89   that subtle effects  of temperature variations on fault rock properties, such as thermal

90   conductivity, could lead to significant effects on fault weakening.

91   Given that temperature evolution is directly coupled to slip history and strength through

92   dissipation of mechanical energy, the strength evolution and the resulting dynamics of

93   earthquakes are expected to be controlled by thermo-mechanical feedbacks.

94

95   Here, we aim to investigate the role of slip history on the the frictional response of rocks, and test

96   the compatibility of laboratory-derived strength evolution with elastodynamics. We use a slip

97   history that is representative of earthquake source-time functions in the form of a so-called

98   "modified Yoffe function" as derived by Tinti et al. (2005) (see Methods section), and test a

99   range of initial accelerations for a fixed total slip (Figure 1). We first explore the physical

100  mechanisms that give rise to the observed complex frictional response, and show that thermally-

101  activated mechanisms like flash heating (near the onset of the slip) and viscous creep (at late

102  stages) are broadly consistent with the observed frictional response. This agreement confirms the

103  key role of temperature and temperature history in the high velocity frictional behaviour of

104  rocks. We then analyse the compatibility of our experimental results with the traction evolution

105 expected from a simple elastodynamic slip pulse model. The measured frictional response is not

106 totally consistent with the model in that it shows more abrupt weakening at the onset of slip and

107 too large re-strengthening at the termination of slip. These differences indicate that

108 elastodynamics would likely produce either shorter slip pulses or sharper drops in slip rate at the

109 tail end of pulses (self-healing).

## 2 Methodology

111

**Figure 1** Yoffe function slip plotted as a function of time (a) and associated temporal
derivatives, velocity (b) and acceleration (c)  imposed during experiments presented in this
manuscript, functions were produced following the closed form solution in  Tinti et al. (2005).
Here $t_s$ is the smoothing time (see main text).

116 Our experiments are analogous to slip on a single point on a fault, and we therefore need to

117 select an appropriate slip function representative of a rupture propagating through a single point

118 in space. In practise it is not possible to define a unique solution since fault slip history depends

119 on the interactions between fault strength and elastodynamics, however there are several

120 candidates we may choose to represent the seismic source (Kostrov, 1964; Madariaga & Nielsen,

121 2003;Tinti et al., 2005; Yoffe, 1951). The Yoffe function represents an attractive solution to

122 model slip history due to its direct compatibility with elastodynamic rupture propagation

123 (Nielsen & Madariaga, 2003; Tinti et al., 2005), and the fact that it shares similarity to slip

124 histories observed in experimental studies (Berman et al., 2020; Rubino et al., 2017). It is

125 characterised by a singular acceleration at the moving crack tip, corresponding to the crack tip

126   stress concentration, followed by an inverse square-root decay in velocity with respect to time

127   (Figure 1b). This results in slip that is approximately square root in time at a fixed observation

128   locality (Figure 1a). Given that singular acceleration is unrealistic in nature, and also not possible

129   to simulate in the laboratory, we used a regularised form of the Yoffe function presented in Tinti

130   et al. (2005). The solution is equivalent to convolving a true Yoffe function (with singular

131   acceleration) with a triangular function of time duration, $t_s$, defined as the smoothing time. Small

132   values of the smoothing time generate more impulsive, shorter duration events i.e. faster initial

133   accelerations, and increasing $t_s$ generates longer duration, less impulsive events (Figure 1). In

134   experiments, the rise time $t_r = 2$ s, and maximum displacement, $U_{tot} = 1.65$ m, were kept constant,

135   to simulate seismic slip equivalent to a typical $M_w = 7$ earthquake (Wells and Coppersmith,

136   1994). We varied $t_s$ from 0.05 to 0.8 s, which may be considered analogous to varying the

137   rupture velocity (Cochard & Madariaga, 1994).

138

139   We utilised a slow to high velocity rotary shear apparatus (SHIVA, Di Toro et al., 2010)

140   installed in the HPHT laboratory at INGV in Rome.  The apparatus is capable of applying up to

141   70 kN of axial load using an electromechanical piston (Bosch-Rexroth EMC105HD), which is

142   servo controlled at a frequency of 8 kHz. A 300 kW motor servo-controlled at 16 kHz drives the

143   rotary motion up to 3000 RPM, we achieved an instantaneous acceleration of $<80$ m/s$^2$ and a

144   deceleration of  $<60$ m/s$^2$ (figure 1c); outside of this range machine vibrations were too strong to

145   gather reliable data. Displacement was measured using a high resolution encoder (6297600 divs)

146   for low velocity ($< 0.15$ m/s) and a low resolution encoder (4000 divs) for high velocity ($\geq 0.15$

147   m/s), the encoder-derived velocity (Figure 2 grey curves) and the imposed velocity function

148   (Figure 2 black curves) show good agreement. Annular cohesive samples of Etna basalt and

149    Carrara marble of 50 mm external and 30 mm internal diameter were prepared for testing, and

150    were squared using a lathe before being ground with #80 grit prior to experimentation. All tests

151    were performed at a normal stress of 10 MPa. Torque was measured using an S-type load cell on

152    the stationary side of the apparatus and all data was logged at 12.5 kHz. A total of over 60

153    simulated slip events are presented in this study (see section 1 in supplementary material). In the

154    majority of experiments slip pulses were repeated using the same sample, with the normal load

155    kept constant during a minimum time period of at least 20 minutes between individual pulses.
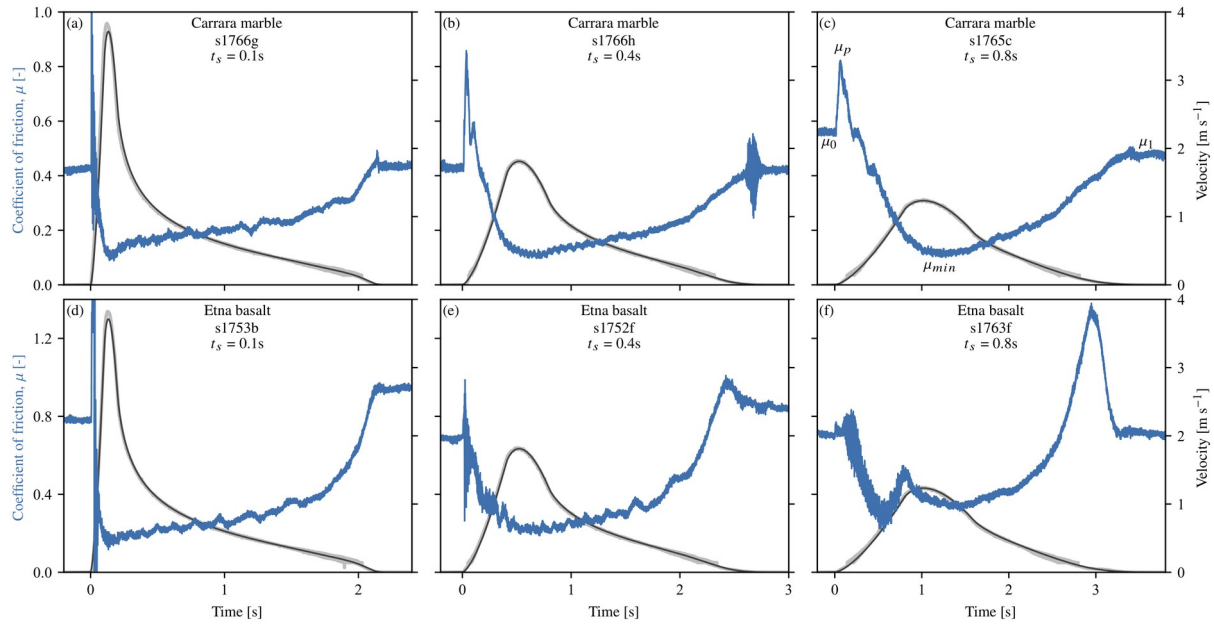

156

157

## 3 Experimental results

159

160

**Figure 2** Frictional response of simulated faults during application of Yoffe functions of varying smoothing time. Panels a)-c) show Carrara marble with increasing values of the smoothing time from left to right (0.1 to 0.8), panels d)-f) show Etna basalt frictional response for the same slip histories as a)-c). Velocity history is shown for reference, where the thicker grey curve represents the encoder derived velocity history, and the black the imposed control signal. Panel c) is labelled according to the frictional parameters identified in the main text.

167

168 All experiments show three stages of behaviour typical of high velocity friction tests: (i) An

169 elastic loading and slip-strengthening phase, which corresponds to an increase in friction

170 coefficient from an initial value at zero velocity, $\mu_0 = 0.5$–$0.6$ ($\tau_0 = 5$–$6$ MPa), to a peak as slip

171 rate increases, $\mu_p = 0.6$–$0.8$ ($\tau_p = 6$–$8$ MPa, Figures 2b and 2c); (ii) A breakdown phase past the

172 peak in frictional strength, where friction drops from $\mu_p$ to a minimum weakened value, $\mu_{min}$,

173 which is generally coeval with the peak in velocity. Values of $\mu_{min}$ are typical of high velocity

174 friction, with values around $\mu_{min} = 0.05$–$0.2$ ($\tau_{min} = ¿0.5$–$2$ MPa) in marble (Figure. 2a)-c)), and

175 $\mu_{min} = 0.2$–$0.3$ ($\tau_{min} = 2$–$3$ MPa) in Etna basalt (Figure 2d)-e)); (iii) A final slip restrengthening

176  phase, where frictional strength increases steadily to a final value, $\mu_1$, as slip rate decelerates,

177  corresponding to the end of the experiment. In Carrara marble the strength typically recovers to

178  $\mu_1 = 0.4–0.5$ ($\tau_1 = 4–5$ MPa, Figure 1a-c), by contrast, for Etna Basalt the strength recovery can

179  become large during deceleration, increasing with $t_s$ (Figure 2d and f). At the largest values of $t_s$

180  = 0.8s, during the restrengthening phase, the frictional strength in basalt reaches an apparent

181  value of $\mu = 1–1.2$ (10–12 MPa), before reducing to $\mu = 0.6–0.9$ (6–9 MPa). In tests where this

182  behaviour was observed the sample often failed in a brittle manner with audible cracking coeval

183  with the peak in friction.

184

185  When comparing between experiments we observe a clear dependence between the overall

186  frictional behaviour and the imposed smoothing time. Inspection of tests with $t_s = 0.1$s (A $\approx$60m/

187  $s^2$, Figure 2a) and d)) shows an almost instantaneous drop in friction, with weakening achieved

188  on a timescale similar to $t_s$. As $t_s$ is increased from 0.1 to 0.4s (Figure 2b) and e)) we observe an

189  increase in the weakening timescale, and by extension an increase in the weakening distance.

190  This trend continues to the largest values of $t_s = 0.8$ (A $\approx$0.7m/s$^2$ Figure 2c) and f)), where the

191  weakening timescale is of similar value to $t_s$. In order to quantify how the smoothing time $t_s$

192  influences the overall mechanical behaviour of the simulated faults, we now estimate key

193  quantities relevant to the energetics of faulting.

194        3.1 Weakening distance

195

**Figure 3** Scaling of the weakening distance with the smoothing time, $t_s$. Filled circles represent
measurements derived from experiments with Carrara marble, open square symbols are Etna
Basalt. The top scale shows the acceleration rate, $A = V_{max}/t_s$, corresponding to the smoothing
timescale on the bottom x-axis defined by the relationship $A = 0.5t_s^{-1.5}$.
200    The coseismic weakening distance is an important parameter governing the propagation of

201    earthquake rupture, providing an indication of rupture efficiency (Ida, 1972). It may also provide

202    insight into the weakening mechanisms active during experiments (Hirose & Shimamoto, 2005;

203    Niemeijer et al., 2011). To estimate the weakening distance, $D_w$, we consider the distance at

204    which strength decreases by 95% and use the same formulation as Hirose & Shimamoto (2005)

205    and fit data using a least squares regression.  The fitted values range from 0.05–1 m for the

206    presented experiments (see supplementary table S1), and are strongly dependent on the slip

207    function applied, but are within the range of values presented in previous studies under similar

208    experimental conditions (Chang et al., 2012; Niemeijer et al., 2011). A clear trend is observed

209    between $t_s$ and $D_w$ (Figure 3), given that smaller values of $t_s$ correspond to a larger acceleration

210    demonstrating an inverse dependence on the initial acceleration. For example, for Carrara marble

211    (Figure 3 filled circles), at $t_s$ =0.05s ($A \approx 80m/s^2$) $D_w$ = 0.08 m, whereas for $t_s$= 0.8 ($A \approx 0.7m/s^2$),

212    the weakening distance increases to $D_w$ =0.6 m, representing an order of magnitude change. A

213    similar order of magnitude increase is observed in Etna basalt (Figure 3, open squares), with $D_w$

214    $= 0.1$m at $t_s =0.1$s (A $\approx 16$ m/s$^2$), increasing to $D_w = 0.5$-$0.9$m at $t_s =0.8$s (A $\approx 0.7$m/s$^2$). It should

215    be noted that values of $D_w$ for Etna basalt become increasingly scattered as $t_s$ increases.

216

217    **3.2 Energy dissipation**

218

220    **Figure 4** Partitioning of breakdown work (a) and c)) and restrengthening work (b) and d)) during
221    simulated Yoffe pulses of varying initial acceleration rates for Carrara marble (a) and b)) and
222    Etna Basalt (c) and d)).

223    Following previous literature, we define the breakdown work $W_b$ [MJ m$^{-2}$], according to the

224    general definition of Abercrombie & Rice (2005),

$$W_b = \int_0^{D_w} \left[ \tau(D) - \tau_{min} \right] dD, \tag{1}$$

225 Where $D_w$ is the displacement when $\tau = \tau_{min}$. We also define restrengthening work, $W_r$, in a

226 similar manner, accordingly:

$$W_r = \int_{D_w}^{D_{tot}} \left[ \tau(D) - \tau_{min} \right] dD, \tag{2}$$

227 Both of these parameters were calculated by numerical integration of the experimental shear

228 stress record with respect to slip (see Nielsen et al., 2016). This provides a quantitative estimate

229 of energy partitioning during experiments. We find that both $W_b$ and $W_r$ depend strongly on the

230 impulsiveness of the Yoffe function applied. Faster initial acceleration rates result in smaller

231 values of $W_b$ and larger $W_r$ (Figure 4). For example for $t_s = 0.075$s ($A \approx 80$m/s$^2$), $W_b = 0.2$ MJ/m$^2$

232 for both marble (Figure 4a) and basalt (Figure 4c), whereas for $t_s = 0.8$s ($A \approx 1$m/s$^2$), $W_b = 0.8$

233 MJ/m$^2$ for marble and $W_b = 0.9$ MJ/m$^2$ for basalt. An inverse relationship is observed for the

234 restrengthening, with shorter deceleration time periods generally resulting in a reduction in $W_r$

235 (Figure 4b and c). For example when $t_s = 0.8$, $W_r = 0.3$ and 0.4 MJ/m$^2$ for marble and basalt

236 respectively, and for $t_s = 0.1$, $W_r$ increases to 1.2 and 1.4 MJ/m$^2$ for marble and basalt

237 respectively. The restrengthening work is generally larger for basalt than it is for marble for a

238 given $t_s$ or initial acceleration rate.

239

240 **4 Driving processes of frictional evolution in the presence of complex slip velocity histories**

241

242 Our results show that strong variations in slip rate induce correspondingly strong variations in

243 frictional strength, with a rapid weakening at high slip rate and significant restrengthening as slip

244 rate decreases. In order to identify the key driving mechanisms responsible for these variations,

245 here we test whether such variations are captured and predicted by existing physics-based high

246 velocity friction laws.

247

248 One key experimental observation is that the minimum strength is almost systematically

249 occurring at the peak velocity achieved during the tests (Figure 2), which corresponds to a

250 velocity-weakening behaviour of the rocks. Such a behaviour is typically associated with some

251 state evolution, whereby instantaneous changes in slip rate should induce strength increase,

252 followed by adjustments towards a lower strength state. Here, the observation of direct

253 correlation between peak slip rate and minimum strength indicates that this state evolution

254 occurs over time (and slip) scales much smaller than that of the change in slip rate imposed in the

255 experiments. This is consistent with models where state was assumed to evolve over slip

256 distances of the order of tens of microns, indeed much shorter than the slip scales measured here

257 (e.g. Noda et al., 2009). Therefore, we primarily focus on a description of strength that excludes

258 considerations of short-slip state evolution.

259

260 Firstly, we focus on predicting the strength of experiments using Carrara marble. We explore two

261 commonly proposed descriptions of strength, flash heating (Goldsby & Tullis, 2011; Proctor et

262 al., 2014; Yao et al., 2016) and grain size sensitive creep (De Paola et al., 2015; Pozzi et al.,
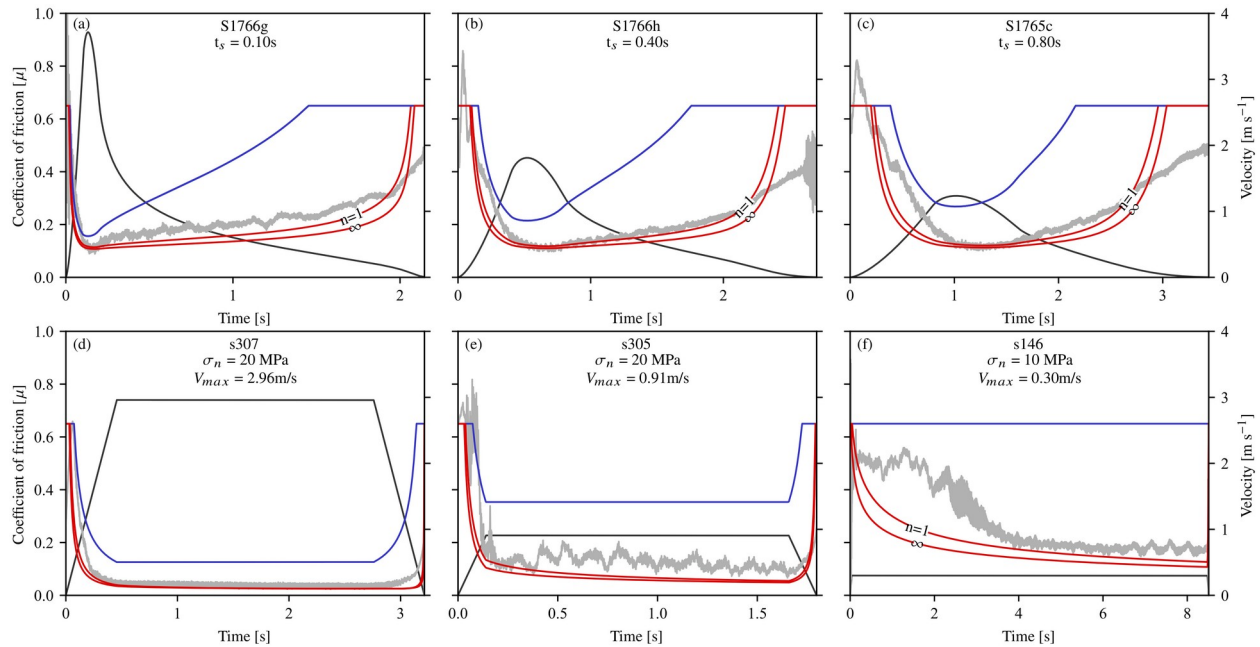

263    2018; Violay et al., 2019), focussing on accurately modelling experimental boundary conditions.

264    Then we discuss the frictional behaviour of Etna basalt hosted faults, and provide a simple

265    comparison to previous models of high velocity friction for melt accommodated weakening.

266    **4.1 Flash heating**

267    Weakening by flash heating (FH) is based on the idea that contacting asperities at the sliding

268    interface dramatically weaken at some threshold temperature (Beeler et al., 2008; Rice, 2006).

269    High velocity experimental data obtained using simple slip rate histories have been shown to be

270    in general agreement with this model (Goldsby & Tullis, 2011; Proctor et al., 2014; Yao et al.,

271    2016). The shear strength is assumed to be given by $\tau = f \, \sigma_n$, where the friction coefficient $f$

272    behaves as

$$f = f_w + \left(f_0 - f_w\right)\frac{V}{V_w\left(T - T_w\right)}, \qquad (3)$$

273    $f_0$ is the low velocity coefficient of friction, $f_w$ the weakened coefficient of friction and $V_w$ a

274    critical weakening velocity that depends on the difference between the ambient fault temperature

275    $T$ and a critical weakening temperature $T_w$. The critical velocity defines a threshold at which a

276    contacting asperity spends a portion of its lifetime above the prescribed temperature $T_w$

277    corresponding to some weakening process, e.g., mineral decomposition (see Supplementary

278    material section 2 for further details). Here we also explore the impact of temperature dependent

279    asperity strength and size, which vary according to an asperity stress exponent, $n$.

280

**Figure 5** Flash heating models compared to experiments with Carrara marble. Blue curves
represent a purely velocity dependant friction law, red curves indicate models where background
temperature rise considered. Curves are labelled according to the value of the asperity stress
exponent. Insets a) to c) represent experiments conducted with Yoffe slip histories, whereas d) to
f) are reproduced from *Violay et al. (2013)* and were conducted with box-car slip histories.

Using the velocity histories imposed in the experiments, we first modelled fault strength with a

fixed ambient temperature (Figure 5, blue curves), i.e., purely velocity-dependent strength.

Comparison of this model directly with our experimental data shows that for all cases, purely

velocity dependant strength is initially consistent with weakening behaviour but diverges with

increasing time. When fully accounting for the rise in background temperature, modelled by

introducing the bulk heat dissipation and diffusion in the rock (e.g., Proctor et al., 2014; see

Supplementary Materials, Section 2), the model predictions significantly improve (Figure 5 red

curves), and strength predictions are generally accurate at short timescales (t < 2s). However, the

models still tend to diverge from the data at larger timescales. Particularly good model

agreement is found for the shortest duration Yoffe slip history experiment (Figure 5a), with the

strength well predicted by the numerical models. The flash heating model does not match

297   restrengthening well for any of the experiments conducted with yoffe velocity history. Changes

298   in the value of the asperity stress exponent result in marginal changes to the strength predictions,

299   when n = 1 the predicted weakening is slower, and strength recovery onsets earlier, reflecting the

300   dominance of asperity strength loss in similarity to Passelègue et al. (2014).

301

302   To place the modelling results in the context of previous results we also compiled data from

303   experiments performed at similar conditions in SHIVA, where 'box-car' slip histories i.e.

304   constant acceleration to constant velocity followed by a constant deceleration to zero velocity,

305   were employed (Violay et al., 2013, 2019). Experiments run at a range of velocities are

306   reproduced and compared to models of flash heating (Figure 5d-f), and are shown to highlight

307   that all model predictions tend to overlap at high constant velocity. This overlap tends to

308   obfuscate the determination of realistic model parameters, particularly at the highest velocities, at

309   least for the range considered here. At relatively low velocity conditions differences are observed

310   between individual models (V = 0.3 m/s, Figure 5f). In agreement with experiments where slip

311   rate was given by Yoffe functions, we observe that a reasonable prediction of data can be

312   obtained when n = 1.

313

314   A consistent observation in all flash heating models is that they significantly over-predict the

315   restrengthening behaviour, and demonstrate that addition of temperature dependant asperity

316   properties does not significantly improve the prediction of strength. An improvement may be

317   yielded by accounting for a log normal distribution of asperity sizes which is a smooth function

318   of velocity (Beeler et al., 2008), which may be more representative of the geometry of
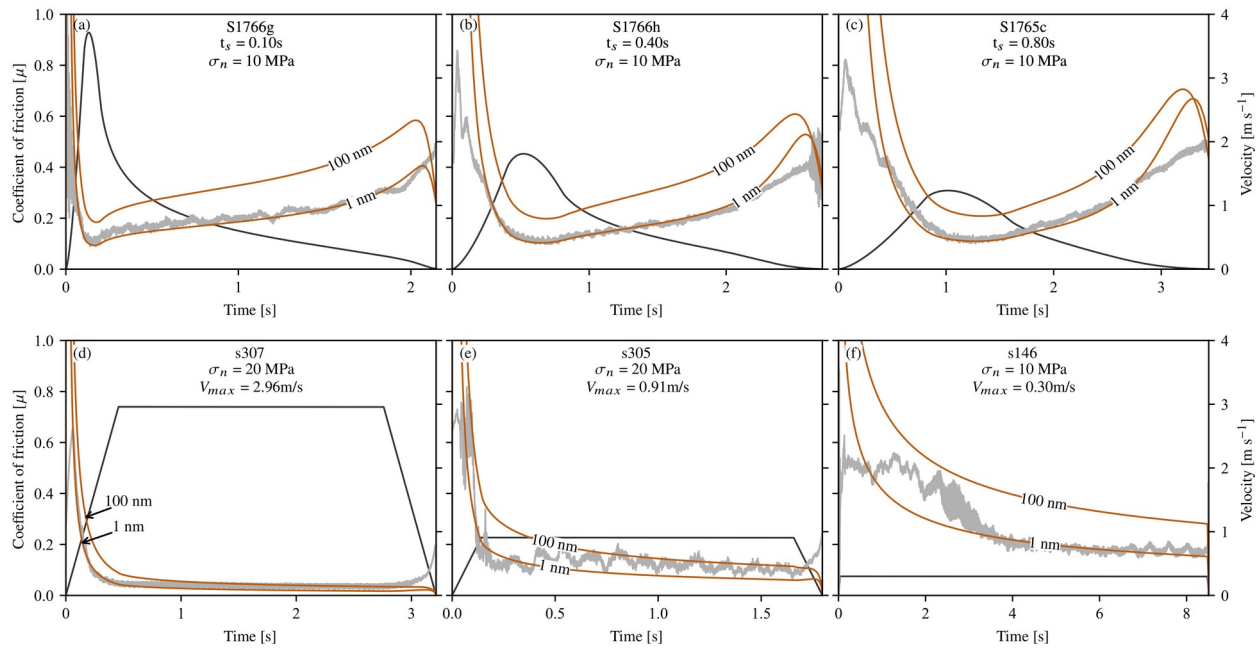

319   experimental surfaces (Candela & Brodsky, 2016).

320

### 4.2 Grain size sensitive creep

Another proposed model of high velocity fault strength in Calcite rich faults is grain size

sensitive creep (GSS). This is motivated by observations of nanometric grains within

experimental and natural fault zones coupled to the expectation of high temperatures resulting

from frictional heating of the slip zone (Demurtas et al., 2019; De Paola et al., 2015; Pozzi et al.,

2018). Here we check consistency of our data with direction predictions from a GSS creep law

derived from deformation of fine grain calcite aggregates at high pressure temperature conditions

(Schmid et al., 1977):

$$\tau \propto \dot{\gamma} d^{-m} e^{\frac{E_a}{RT}}, \tag{4}$$

where $\dot{\gamma}$ is the shear strain rate, $d$ is the grain size, $m$ is the grain size exponent, $E_a$ is the

activation energy and $R$ is the gas constant (see Supplementary material S1, for detailed

parameter values and modelling assumptions). Similarly to our computations using flash heating,

we fully account for the background temperature evolution in the rock with temperature

333     dependant thermal diffusivity.

**Figure 6** GSS creep models (red) compared with experimental data (grey solid lines). Curves are labelled according to grain size used in model runs. Insets a) to c) are Yoffe slip history experiments and d) to f) are reproduced experiments from *Violay et al. (2013)* with "box-car" slip histories. All experiments are the same as in figure 5.

340    Results from GSS models systematically overpredict the strength of faults at short timescales,

341    and do not predict the initial weakening for all values of $t_s$ (Figure 6a, b and c). However, from

342    the late stages of weakening, up to the later stages of restrengthening we observe a good

343    prediction of strength evolution. When $t_s = 0.1$ s the restrengthening is well matched, however

344    for larger values of $t_s = 0.4$ s and 0.8 s, GSS models systematically predict a faster

345    restrengthening rate during the final deceleration period than experiments. At cessation of slip, as

346    velocity decreases below ~1 mm/s, the model predicts a complete loss of strength at all

347    conditions consistently with the GSS flow law (Figure 6a, b and c). The prediction of zero

348    strength when compared to the experimental data suggests that GSS may no longer

349    accommodate deformation during the final stages of slip. A grain size of 1 nm is systematically

350    required to predict the strength of faults with Yoffe velocity history (Figure 6 a-c). Again, for

351    comparison purposes, results are shown from Violay et al., (2013) and Violay et al., (2019). With

352    GSS models a reduced degree of convergence is observed at constant velocity, although the same

353    grain sizes show a generally similar behaviour at large timescales where sliding velocity is high

354    (V >= 1 m/s, Figure 6d and e). A reasonable agreement between models and data is observed for

355    a box-car slip history at velocity of 0.3 m/s (fig 6f), identifying the wider applicability of the

356    creep model across the range of sliding velocities.  Again, 1 nm grain sizes are required to

357    accurately predict the strength of experiments conducted with a box car velocity history at low

358    velocity, low normal stress conditions (Figure 6f), however use of a 100 nm grain size shows

359    good agreement with the higher velocity experiments (fig 6d and e).

360

361    The nanometric grain size required to match fault strength is probably unrealistic (De Paola et

362    al., 2015; Pozzi et al., 2018; Violay et al., 2013). However, this could be remedied by using a
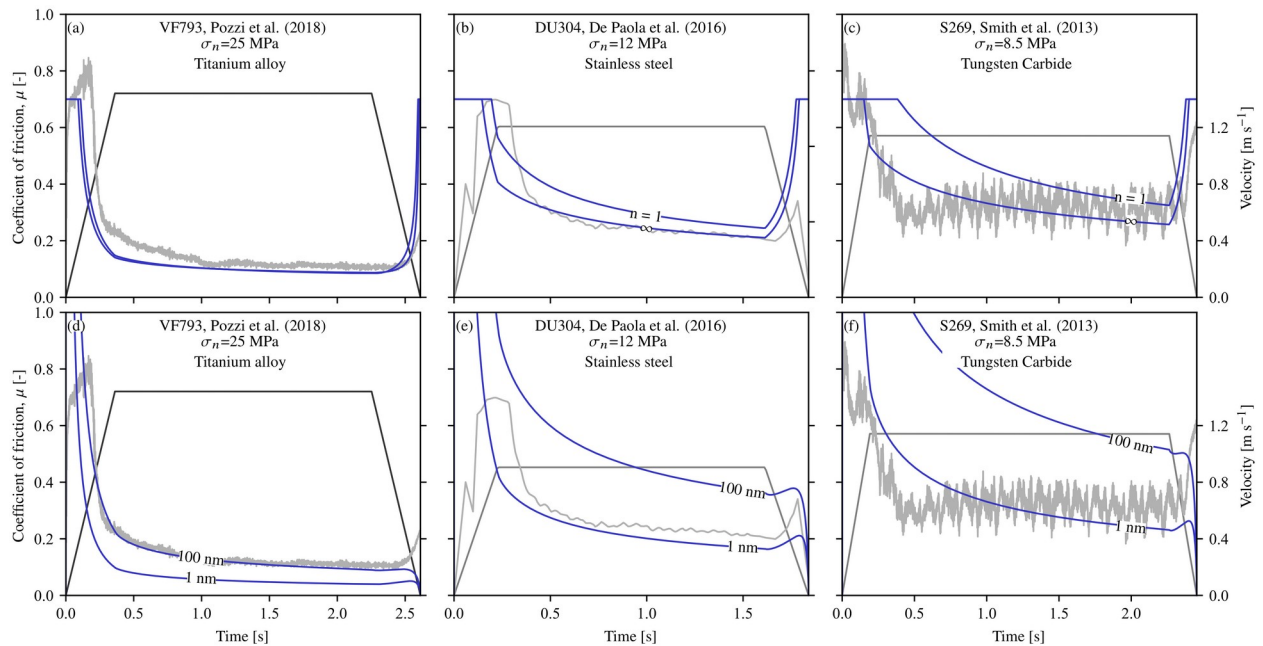

363    modified, much larger value for the preexponential factor in Equation 4; here, we decided to use

364    an empirical estimate from an exisiting dataset obtained at low strain rate, but several physical

365    phenomena might dramatically change that value. Pre-exponential factors include contributions

366    from grain boundary geometry (thickness and roughness) and grain boundary self-diffusion

367    (Poirier, 1985). It is possible that the fault microstructure during initial weakening, which has

368    been demonstrated to result from dislocation avalanches (Spagnuolo et al., 2015), may result in

369    anhedral nanograins with larger grain boundary aspect ratio when compared to the final

370    microstructure which is likely to have annealed during cooling of the fault. Raj & Ashby (1971)

371    demonstrated that increases in the aspect ratio of contacting grain boundaries increases the self-

372    diffusion coefficient, resulting in reduced yield stress, which may preclude the need for

373    unrealistically small grain sizes.

374

375    It is also important to consider that if flash processes occur during initial fault weakening,

376    temperature may be locally higher than predicted from GSS models. An initial flux of heat

377    resulting from asperity-scale processes may be sustained throughout the test duration (Aretusini

378    et al., 2020), which would allow larger grain sizes to give quantitative agreement with the

379    experimental data. We also note that in Violay et al. (2019) the authors were able to match the

380    final fault restrengthening of the data presented in Figure 6d) by accounting for heat loss in two

381    dimensions.

382

383    **4.3 The importance of accurate temperature history**

384

385    Both the flash heating and grain size sensitive creep models demonstrate the importance of

386    incorporating temperature history into the models, and shows that it is important to consider

387 appropriate thermal properties in model boundary conditions. This point was first highlighted by

388 Yao et al. (2016) where experiments were conducted using sample holders of varying thermal

389 diffusivity, demonstrating that varying temperature histories give differing strength evolutions.

390 Here we further test this hypothesis by comparing the output of both FH and GSS models by

391 using previously published calcite gouge experimental data obtained with a range of sample

392 holders of varying diffusivity (Cverna, 2002). We consider, in order of increasing thermal

393 diffusivity, grade 4 Titanium alloy (Ti90Al6V4, Pozzi et al., 2018), AISI 316 stainless steel (De

394 Paola et al., 2015) and tungsten carbide (Smith et al., 2013). We approximate each experimental

395 geometry as closely as possible in 1D, with the principal slip zone localised asymmetrically on

396 the boundary between the gouge layer and the sample holder with appropriate thermal diffusivity

397 (De Paola et al., 2015; Pozzi et al., 2018a; Smith et al., 2013, see supplementary material S1).

398

399

400 **Figure 7** Effects of varying thermal diffusivity in full thickness models (blue curves) with
401 realistic sample boundary conditions compared to previously published experimental data (grey
402 curves). Panels a) to c) are modelled using the flash heating model described in previous
403 discussion, with fixed thermal diffusivity with curves labelled according to the asperity stress
404 exponent used. Panels d) to f) show the same experimental data, however this time using the

405 GSS model defined in the previous discussion with fixed thermal diffusivity, curves are labelled
406 according to the grain size used in the model prediction. Thermal diffusivity increases from the
407 left to right of the figure.

408

409 For both rheological models we observe that for increasing thermal diffusivity, the fault strength

410 predictions increase, consistently with experimental observations (Figure 7). Generally FH does

411 not predict the initial weakening behaviour, predicting faster weakening in Titanium alloy

412 (Figure 7a) and Stainless steel (Figure 7b), and less abrupt weakening for tungsten carbide

413 (Figure 7c). The differences in model predictions and experimental data may result from strain

414 localisation and grain crushing that occurs during early stages of slip in gouges (Logan et al.,

415 1992). During steady state sliding conditions the FH models are able to predict strength

416 evolution with reasonable success, and in particular predict a slow progressive weakening with

417 slip resulting from a progressive temperature rise, sharing similarities to the experimental data

418 (Figure 7a, b and c). The restrengthening is systematically over predicted by the flash heating

419 models, similarly to the results shown in the previous section.

420

421 Initial weakening is predicted comparatively better for GSS than it is for FH. Similarly to FH, the

422 GSS models also predict progressive weakening observed during constant velocity conditions

423 (e.g. Figure 7e). The restrengthening rate predicted by models is slower than observed in

424 experiments, and consistently with previous discussion of GSS models, strength falls to zero as

425 slip arrests. Generally we observe that the best predictions of fault strength for the gouge

426 experiments are obtained for the previously used parameter set, except at the highest normal

427 stress conditions. Given that we may use the same parameters in the constitutive friction law (FH

428 or GSS), it suggests that the key variable is the bulk temperature evolution. In short, reconciling

429 these individual experimental observations is difficult without carefully considering model
430    boundary conditions and demonstrates that it is of fundamental importance to accurately capture

431    on and off-fault thermal boundary conditions accurately, confirming the conclusions of Yao et al.

432    (2016).

433

434    **4.4 Transition in weakening mechanisms**

435    Flash heating predictions are better at shorter timescales, whereas longer timescales demonstrate

436    a better prediction by GSS models. In fact all FH models significantly over predict the final

437    strengthening behaviour. Taken together these observations suggest that a transition in

438    weakening mechanisms is likely to occur. At early stages when the bulk fault temperature is low,

439    and GSS is not efficient, behaviour will be dominated by asperity scale flash heating processes

440    leading to bulk heating of the principle slip zone. However as slip and fault temperature

441    increases, GSS deformation becomes increasingly favourable. This transition has been

442    previously proposed by Pozzi et al. (2018) and De Paola et al. (2015), however they did not

443    explicitly consider FH at early stages of slip, suggesting instead that the transition is simply from

444    cataclastic processes to GSS. If FH was active during early stages of slip it is possible that the

445    high contact temperatures during weakening may be sustained during later stages of the

446    experiment and deformation could be accommodated by larger grain sizes. Effectively the two

447    constitutive equations define a threshold temperature at which fault strength approaches a

448    residual strength. In the case of FH this is given by the temperature at which a generic weakening

449    process occurs (which could be GSS), whereas for GSS it defines the temperature at which

450    efficient diffusive mass transfer occurs, in both the governing state variable is fault temperature.

451

452    **4.5 Weakening and restrengthening in basalt**

453

454    Weakening of basaltic experimental faults is facilitated by frictional melting, which leads to the

455    formation of a hot low viscosity melt layer (Hirose & Shimamoto, 2005; Niemeijer et al., 2011;

456    Rempel & Weaver, 2008; Violay et al., 2019, see videos S3 and S4). Modelling of weakening

457    accommodated by melting has previously addressed by Nielsen et al. (2008) and Rempel &

458    Weaver (2008) who explicitly considered the effects of the effects of progressive melt formation

459    during high velocity sliding. Melting of rock during frictional sliding at high velocity can be

460    shown to result in a complex 2-stage weakening behaviour, reflecting the degree of melt layer

461    formation, with the presence of initially patchy melt leading to strengthening, followed by

462    secondary weakening due to the formation of a continuous meltlayer (Del Gaudio et al., 2009;

463    Hirose & Shimamoto, 2005; Rempel & Weaver, 2008). This is evident in our experiments with

464    slower initial acceleration rates (e.g.$t_s$ = 0.8s, Figure 2f). When acceleration is sufficiently high,

465    then weakening is monotonic (Figure 2d), consistently with Del Gaudio et al. (2009).

466

**Figure 8** Restrengthening phase in basalt, illustrating the relationship between final deceleration and restrengthening behaviour in Etna basalt. Curves are coloured according to the smoothing time, stars indicate where slip velocity falls below a critical rate, W (analogous to $V_w$) as defined in Nielsen et al. (2008).

471     Turning attention now to the restrengthening phase of basalt experiments, we observe a clear

472     relationship between the final deceleration rate and restrengthening behaviour (Figure 8). Where

473     final deceleration is sufficiently rapid, $t_s = 0.1$ s, then no strength overshoot is observed, and

474     friction monotonically increases up to the end of the experiment, with $\mu_1 = 0.9$. As the

475     deceleration rate is decreased as a result of increasing $t_s$, we observe increasing amounts of

476     strength overshoot, and faster restrengthening rates. For the largest value of smoothing time ($t_s =$

477     0.8s), the strength overshoot is considerable, with a coefficient of friction close to 1.4 (Figure

478     8a), almost twice the initial value of $\mu = 0.7$. Such large increases in strength suggest melt

479     solidification and cohesion of the fault, and where large overshoot was observed cracking was

480     heard, identifying that the melt solidified and failed in a brittle manner (see video S4). In the

481     limit of adiabatic instantaneous deceleration, the fault stress would instantaneously drop as a

482     result of the Arrhenius dependance of melt viscosity (Giordano et al., 2008). However where

483     deceleration is slow, heat diffusion dominates and significant strengthening occurs due to melt

484     solidification. According to Nielsen et al. (2008) frictional melt is expected to form or be

485     sustained above a crictical velocity of approximately 0.2 m s$^{-1}$ for Etna basalt. A velocity of 0.2

486     m s$^{-1}$ agrees well with the onset of restrengthening in our experiments, with the magnitude

487     correlating well with the timescale faults spend sliding at velocities less than this rate (Figure

488     8a).

489     **5    Are laboratory friction data compatible with elastodynamics?**

490

491     In the previous section we analysed the potential driving processes that produce the observed

492     evolution of friction in response to an imposed slip history. In nature, during an earthquake, the

493     evolution of frictional strength feeds back into the slip history due to elastodynamic stress

494   redistribution and the requirement of stress equilibrium. To illustrate this, let us consider the

495   elastic stress field associated with anti-plane slip along a fault in 1d:

$$\tau(x,t)=\frac{G}{2c_s}V(x,t)+\int_{\Sigma}\int_0^t K(x-\xi;t-t')V(\xi,t)dt'\,dV, \qquad (5)$$

496   where $G$ is the shear modulus, $c_s$ is the shear wave speed, $V$ the on fault particle velocity, $x$ is

497   the position along the fault, and $K$ the dynamic load associated to points on the fault that are still

498   slipping.

499

500   The dynamic load term in equation 5 is composed of the integrated slip history across the entire

501   span of the rupturing fault. Waves radiated from other points on the fault results in dynamic

502   loading which modifies slip-stress history, typically resulting in a heterogeneous slip history on

503   the fault plane. In addition, the transfer of stress, wave propagation and rupture velocity depends

504   also on the geometry of the rupturing fault, so that the typical non-planar geometry of natural

505   faults will also influence the slip-stress history (e.g., Romanet et al., 2020). Therefore, slip

506   history at a point on a fault is highly non-unique and depends on the entire integrated rupture

507   history, and in practise there is no unique test of elastodynamic compatibility.

508

509   In order to test the compatibility of our experiments with elastodynamics, we must make several

510   simplifying assumptions. To do this we consider a steady-state slip pulse model, where both the

511   rupture velocity and source duration are constant. In this case the elastodynamic equilibrium in

512   anti-plane  geometry can be simplified to

$$\tau(x)=\tau_b+\frac{G^{\dot{\iota}}}{2\pi V_r}\int_0^L \frac{V(s)}{s-x}ds, \qquad (6)$$

513   where $\tau_b$ is the ambient shear stress, $L$ the pulse length (equivalent to the product of rupture

514   velocity and total rise time), $G^{\dot{c}}$ is the shear modulus multiplied by a function of the ratio of

515   rupture speed $V_r$ and shear wave speed. Equation (6) gives the dynamic elastic stress produced

516   by the slip rate distribution along the pulse. In our experiments, the slip rate is imposed as a

517   function of time. Here we consider that this slip rate evolution represents the relative motion of

518   two opposing points along a steadily propagating pulse. Choosing a constant rupture speed, we

519   first compute the elastic stress by direct integration of (6), and compare it to the measured

520   experimental strength (for details of methodology see Viesca & Garagash (2018) and

521   supplementary material S2). Since strength should be equal to stress during slip to satisfy

522   mechanical equilibrium, any deviations between predicted stress and measured strength would

523   indicate inconsistency between the rheological behaviour of the fault and our choice of imposed

524   slip rate.

525

526

**Figure 9** Experimental data compared to elastodynamic solution using steady state pulse model of rupture propagation. Dashed shear stress curves indicate solutions compatible with the imposed velocity history during an experiment, and overlay smoothed experimental data (solid curves, labelled as observed in a)). The solid velocity history is that which is predicted from the measured evolution of shear stress (traction) during an experiment, lines are coloured grey where $V < 0$ m/s.

The stress predicted by imposing the velocity history is only qualitatively compatible with the

overall evolution of strength during tests: there is an initial weakening phase, with strength

536   decreasing until sliding occurs at constant stress after which the stress increases during final slip

537   deceleration, although the precise magnitudes and timings do not agree. In particular, the

538   predicted final stress increase occurs later than in experimental observations, with a

539   comparatively smaller magnitude.

540

541   We can also use our strength measurements to predict what would be the slip rate evolution

542   along a hypothetical pulse, i.e., to determine $V(x)$ based on $\tau(x)$ in (6), assuming this time that

543   strength is equal to elastic stress, and compare this slip rate to the originally imposed

544   experimental slip rate. By imposing zero slip velocity before and after the rupture interval, we

545   also constrain the background stress $\tau_b$ for our hypothetical pulse (see appendix section 3 for

546   details). While there are encouraging similarities between model and observation, the predicted

547   slip rate is quantitatively inconsistent with the imposed one. In particular, the final increase in

548   stress measured in experiments results in back-slip where velocity is negative (e.g. Figure 9k).

549   The prediction of back-slip is not realistic and would not occur during spontaneous rupture.

550

551   Overall, the experimental data show limited compatibility with our simple slip pulse model.

552   Considering that the strength is mostly controlled by slip rate (with short state evolution

553   distances) and temperature, we expect that slip rate and strength evolution that are compatible

554   with elastodynamics would involve abrupt changes in slip rate together with rapid strength

555   changes, both at the rupture tip and at the cessation of slip. For instance, in Carrara marble (e.g.

556   Figure 9a and d, sample S1766g), imposing a relatively constant slip rate after initial acceleration

557   will lead to slowly decreasing strength (due to temperature rise), which is likely to eliminate the

558   possibility of back-slip. Then, an abrupt velocity drop might be consistent with an increase in

559   strength above the elastic stress, producing spontaneous slip arrest.

560

561   The results on Etna basalt further support the requirement for rapid final slip deceleration as the

562   strength increases quickly during melt solidification, resulting in a highly unrealistic minimum

563   compatible slip rate of $\approx$ –2 m/s (Figure 9l), consistent with the notion of melt 'fusion' during

564   high velocity sliding (Fialko & Khazan, 2005).

565   **6   Conclusions**

566   In this work we document results from high velocity friction experiments imposing a realistic

567   source time history, in order to investigate how fault strength evolves during earthquakes. Simple

568   first order observations show that the weakening distance and breakdown work are inversely

569   dependent on the initial acceleration rate. Experimental results combined with modelling

570   demonstrate that the high velocity strength of faults during variable velocity strongly depends on

571   prior sliding history and temperature evolution. Carbonate built fault strength can be accurately

572   predicted by flash heating at small time scales and grain size sensitive creep at larger timescales,

573   provided that model boundary conditions are faithful to experimental conditions. Where flash

574   heating is utilised to model the fault strength of carbonate built faults, then final restrengthening

575   is always over predicted. In the case that a creep constitutive law is used there are some

576   significant differences between requisite grain sizes for accurate strength predictions and

577   observed grain sizes from microstructural observations (De Paola et al., 2015; Pozzi et al., 2018).

578   This discrepancy remains unresolved, and might be due to incorrect assumptions about our

579   choice of deformation mechanism or the estimated temperature. However, the remarkable

580   agreement between model predictions and observations indicates that thermally activated viscous

581   flow laws are good candidates for the rheology of faults at high velocity.

582   These results provide an important validation of constitutive laws of frictional strength under

583   non-constant velocity histories, justifying their use in coupled elastodynamic models, when the

584   temperature rise of the fault is considered (e.g., Brantut & Viesca, 2017; Noda et al., 2009).

585   In our experiments, we imposed a slip rate history and measured the resulting strength. In nature,

586   there is a feedback between strength and slip rate evolution due to elastodynamic stress

587   redistribution. We tested the consistency of our experimental data with a simple elastodynamic

588   model, and found discrepancies, i.e., the measured strength does not match the predicted elastic

589   stress associated with the imposed slip. It is likely that the rheology of the fault gives rise to

590   velocity changes (acceleration and deceleration) more abrupt than in our imposed source-time

591   functions.
