(Dated: 4 September 2020)

We present an inversion methodology where acoustic observations of infrasound waves are used to update an atmospheric model. We sought a flexible parameterization that permits to incorporate physical and numerical constraints without the need to reformulate the inversion. On the other hand, the optimization conveys an explicit search over the solution space, making the solver computationally expensive. Nevertheless, through a parallel implementation and the use of tight constraints we demonstrate that the methodology is computationally tractable. Constraints to the solution space are derived from the spread (variance) of ERA5 ensemble reanalysis members, which summarize the best current knowledge of the atmosphere from assimilated measurements and physical models. Similarly, the initial model temperature and winds for the inversion are chosen to be the average of these parameters in the ensemble members. The performance of the inversion is demonstrated with the application to infrasound observations from an explosion generated by the destruction of ammunition at Hukkakero, Finland. The acoustic signals are recorded at an array station located at 178 km range, which is within the classical shadow zone distance. The observed returns are assumed to come from stratospheric reflections. Thus, the reflection altitude is also an inverted parameter.

I. INTRODUCTION

This work considers the problem of estimating an updated atmospheric model to become consistent with a set of infrasound observations, and the associated problem of identifying the member(s) from an atmospheric reanalysis model ensemble that lie closer to the infrasound-consistent, updated model.

Atmospheric reanalysis models are the result of the assimilation of direct and indirect measurements of different properties of the atmosphere (e.g., [Kazutoshi et al., 2007](#); [Parker, 2016](#); [Uppala et al., 2005](#)). For example, direct measurements of atmospheric winds and temperature are provided by radiosondes up to altitudes of around 30 km. Satellites, on the other hand, provide measurements from which estimations of temperature can be obtained up to altitudes of ~50 km ([Lee et al., 2019](#)).

A better representation of the upper stratosphere in models, especially for winds, can contribute to an enhanced numerical weather prediction on weekly to monthly timescales, especially during winter (see e.g., [Domeisen et al., 2020a,b](#), and the references therein). To this end, efforts are made to adapt and expand at-

mospheric probing infrastructures and technologies to provide additional measurements on the dynamics of the stratosphere (e.g., [Blanc et al., 2018, 2019](#); [Khaykin et al., 2020](#); [Tan et al., 2008](#)).

Over the last decade, there have been significant improvements in global data assimilation capabilities of the lower, middle, and upper atmosphere ([Drob, 2019](#)). General circulation models (GCMs) have been progressively extended to cover the whole stratosphere to better capture stratospheric-tropospheric interactions and improve forecast skill scores ([Charlton-Perez et al., 2013](#); [Siskind and Drob, 2014](#)). However, the mean state and the variability described by Numerical Weather Prediction (NWP) models, such as those distributed by the European Centre for Medium-Range Weather Forecasts (ECMWF), are subject to inaccuracies in both current operational analyses and reanalyses in the altitude range where assimilated observations become sparser (i.e., above 30 km altitude).

Within the Copernicus Climate Change Service (C3S), ECMWF is producing the ERA5 reanalysis, which embodies a detailed record of the global atmosphere. This new reanalysis, based on the Integrated Forecasting System (IFS) Cy41r2, benefits from a decade of developments in model physics, core dynamics and data assimilation. A gain in forecast skills has been shown ([Hersbach et al., 2020](#)), allowing an enhanced description of the

^aismael@norsar.no

evolution of weather systems in the troposphere. ERA5 also provides analyses with better global-mean temperatures in the uppermost troposphere and stratosphere, although it still suffers from temperature uncertainty and bias (Simmons *et al.*, 2020).

There is a current interest from the NWP community to validate model specifications at stratospheric altitudes using independent observations. This includes satellite radiance and additional high-resolution measurements (gravity waves and momentum flux) that are currently not resolved in gravity wave model parameterization schemes (e.g., Charlton-Perez *et al.*, 2013). Given the importance of model validation in the middle and upper atmosphere regions, recent studies focused on comparisons between ECMWF products with independent observations such as long-duration balloon flights (e.g., Podglajen *et al.*, 2014). Wind radiometer and lidar instruments were also used to evaluate the accuracy of NWP models and data-constrained assimilation systems (e.g., Ehard *et al.*, 2017; Le Pichon *et al.*, 2015). The development of innovative high-resolution prototype sounding systems providing in near-real time wind and temperature observations from the ground to the mesosphere and lower-thermosphere (MLT) has stimulated the construction of multi-technology observational platforms detailing the dynamics of the middle atmosphere and interactions between atmospheric layers with unprecedented resolution (Blanc *et al.*, 2018).

Infrasound waves provide complementary information to characterize the middle atmosphere. This is particularly valuable above 30 km altitude where few other currently available technologies provide direct measurements, especially for the dynamics (see e.g., Le Pichon *et al.*, 2019, for a review). As infrasonic waves propagate into the middle atmosphere, small-scale features of the vertical structure of the atmosphere can also be inferred from the characteristics of measured wave parameters (Assink *et al.*, 2019; Chunchuzov and Kulichkov, 2019). Infrasound signals are generated by natural phenomena such as microbaroms, volcanoes and meteorites, as well as by human-activities such as explosions in mines or nuclear tests. The infrasound waves travel along waveguides in the atmosphere, which are formed by vertical variations in wind and temperature. Therefore, similar to seismic waves traveling through the solid earth, the properties of the medium of propagation get encoded along the path of propagation and amplitude of the infrasound waves. Infrasonic signals propagating in stratospheric waveguides are typically refracted or reflected from altitudes near the stratopause where direct measurements are difficult and overly sparse, especially for winds. The sensitivity of the propagation effects to the atmospheric structure near the turning height makes infrasound analysis promising for characterizing this region of the atmosphere.

Through the tool of inverse theory, it is thus feasible to estimate the characteristics of the medium of propagation that explain a set of observations of infrasound data. Such is the effort that has been made by different groups

working with infrasound observations around the world (see Assink *et al.*, 2019, for a review). For example, (Drob *et al.*, 2010) proposed the parameterization of the adiabatic sound speed and wind profiles in 1D atmospheric models in terms of basis functions extracted from the singular value decomposition (SVD) of a population of historical profiles for the area of interest. In this way, the solution space was reduced to the estimation of scalar coefficients that multiplied by the basis functions produced the atmospheric profiles that explained the infrasound observations. Similar approaches were then followed by Lalande *et al.* (2012) and by Assink *et al.* (2013). Arrowsmith *et al.* (2013) and Blom and Marcillo (2017) also investigated the problem from the perspective of an unknown source location, which is a common challenge when working with infrasonic observables.

Model simplification is generally required when working with infrasound observables to estimate atmospheric model updates. The reason is that the number of independent observations is normally much smaller than the number of model parameters to update, which makes the inverse problem strongly ill-posed. Alternatively, the size of the solution space can be reduced by imposing constraints (e.g., Vera Rodriguez *et al.*, 2012; Vera Rodriguez and Kazemi, 2016). In fact, the parameterization proposed by Drob *et al.* (2010) bounds the solution space to those models that are a linear combination of the chosen basis functions. This type of constraint preserves the most significant statistical properties of the atmosphere within the time span of the population of profiles used in the SVD, although it can be limiting or of little help in regions and/or time periods with dynamic atmospheric conditions.

Previous efforts to solve the inversion have resorted to parameterizations that follow the classical least-squares formalism, either based on Fréchet derivatives (Lalande *et al.*, 2012) or with a Bayesian formulation (Assink *et al.*, 2013). These attempts introduced additional model simplifications, such as fixing some of the profiles during the inversion (e.g., adiabatic sound speed), and/or inverting only for the upper atmospheric layers of the models.

In the current work, we consider a more general representation of the problem, in which the inversion is achieved via a solver of the heuristic type. The objective is to minimize a cost function, where the cost can be estimated either via least-squares or any other ad hoc metric. This offers flexibility not only to select convenient metrics to assess the merit of a solution, but also to easily incorporate different types of constraints without the need to reformulate the optimization, for example, by recalculating partial derivatives. In fact, the cost function does not need to be differentiable as required in classical methods using least-squares minimization. To alleviate the ill-posedness of the problem, we bound the temperature and wind profile solution space to a region in the vicinity of the members of ERA5 ensemble reanalysis models (from now on ERA5-ensembles, Hersbach *et al.*, 2019; Hersbach and Dee, 2016). Then, we solve the opti-

mization using a heuristic-learning algorithm previously developed to solve a similar inversion problem in passive seismics (Vera Rodriguez, 2019). In this way, we not only estimate an updated model consistent with our infrasound observations that is useful on its own, but also identify the members of the ERA5-ensemble that lie closer to it. These members should then be preferred in further uses of the ensembles or to calibrate the preparation of the ensembles themselves. The performance of the method is demonstrated using observations of infrasound waves produced by regular explosions at a site in Finland (Gibbons *et al.*, 2015, 2019).

Recently, Vanderbecken *et al.* (2020) also looked at the problem of identifying members from ensemble models that were more likely representative of the atmospheric state based on their consistency with infrasound observations. The approach was applied to infrasound signals generated by the Mount Etna volcano. In this case, backazimuth and trace velocity observations were input to a Bayesian algorithm, which assigned a likelihood to each of the ensemble members. Different from the work presented here, updating the input atmospheric models was not within the scope of that study.

Also recently, Amezcua *et al.* (2020) performed an off-line data assimilation experiment where an Ensemble Kalman filter was applied to update the representation of cross-wind estimations into ERA5-ensembles. The cross-winds were estimated based on the measured travel-time and backazimuth deviation of infrasound arrivals from 598 explosions and an analytical formula (Blixt *et al.*, 2019, see Section II in this article for further descriptions and references regarding this explosion dataset.). In this case, a single value of cross-wind was assimilated to update a particular model. This limits the constraint that is attainable with the infrasound information. Therefore, in this work we opt to use the three primary observables derived from the infrasound data (i.e., backazimuth, trace velocity and travel time).

In short, the contributions of this work can be summarized as: inverting for atmospheric wind and temperature profiles without restricting the solution space to atmospheric states that are linear combinations of previous states. Instead, we constrain the inversion by bounding the solution space with uncertainties that summarize the current atmospheric knowledge from direct and indirect measurements, and physical models. As a result of the inversion setting, our results can be directly related to the ensemble models used to bound the solution space, so that, the members of the ensemble that are more consistent with the infrasound observations can be identified.

We start the description in the following section by introducing the infrasound dataset and atmospheric models used to test the inversion. Thereafter, the parameterization of the problem is described together with the strategies followed to bound the solution space and achieve the optimization. Finally, we present detailed results of the inversion applied to an explosion from the real dataset, followed by our conclusions and future directions

of work. Additional example results are also provided as complementary information.

II. THE HUKKAKERO EXPLOSION DATASET AND THE ATMOSPHERIC MODEL ENSEMBLES

The Hukkakero dataset consists of a series of explosions that happen regularly during August and September at the site of Hukkakero in Finland (67.94° N, 25.84° E) (Gibbons *et al.*, 2007; Lyszka and Kvaerna, 2008). Both seismic and infrasound waves generated by the blasts are regularly detected at the array station ARCES (69.53° N, 25.51° E) located in northern Norway. Gibbons *et al.* (2015, 2019) described details of the dataset, including the processing conducted to extract the parameters arrival back azimuth (θ_{obs}) and trace velocity (v^{app}). Apart from θ_{obs} and v^{app} , total propagation time (T) is also an observation. Therefore, any one explosion provides with three points to fit during an inversion process (i.e., under the knowledge of the source position).

Blixt *et al.* (2019) estimated the uncertainty of the backazimuths extracted from this dataset to be in the range of 1.0° to 1.5°. Following a similar analysis for the apparent velocity yields uncertainties on the order of 10 m/s. Taking into account that these uncertainties are approximations obtained with an empirical analysis (see Blixt *et al.*, 2019, Section 2C for details), we consider more conservative values of 0.5° and 5 m/s for the inversion process. Our array processing output and coherence time series are calculated over sliding 10 s windows, stepped with 1 s increments (an example from this dataset is presented in Figure 4 of Blixt *et al.*, 2019). We use the estimated trace velocity and backazimuth at the coherence peak, and a tolerance of 1 s is also set in the code when fitting the observations – hence reflecting a first order assumption of the temporal uncertainty of the selected point in the array output parameter series. However, we notice that this premise is rather simplistic because the coherence curve can build up and fall off slowly around its peak depending on, e.g., the signal-to-noise ratio, how impulsive and energetic the most coherent segment of the wavetrain is, the length of the sliding time window, as well as on the dominating wave period within the analyzed frequency pass-band. Although the algorithm performed well in our tests requesting these levels of fit with the observations, other datasets may require less stringent fitting criteria.

As noted in Blixt *et al.* (2019), ARCES is located within the classical shadow-zone distance from Hukkakero, suggesting that the arrivals detected at the station correspond to stratospheric reflections rather than refracted waves (e.g., Chunchuzov *et al.*, 2015a,b). Using ray tracing for a fan of shooting elevation angles through ERA-interim atmospheric reanalysis models, Blixt *et al.* (2019) conducted a grid search to estimate the reflection-altitudes that minimized the difference between modeled and observed propagation times for 598 Hukkakero explosions. This exercise assumed that the

atmospheric models represented the infrasound propagation reasonably well.

Since the objective of the inversion developed in the current work is to update the atmospheric models, the reflection altitude that explains an observed propagation time must also be updated in a self-consistent manner. This is achieved by including this altitude as part of the inverted model parameters.

The atmospheric models to update with the inversion are extracted from the ERA5 ensemble product. The ERA5-ensembles are the latest type of reanalysis models generated by the ECMWF. This product has global coverage and assimilates observations from satellites, land stations, buoys, radiosondes, aircrafts and ships. The ensemble models are available at 3-hour intervals with a 63 km horizontal resolution in 137 vertical levels from surface up to an altitude of 0.01 hPa, i.e., around 80 km (Hersbach and Dee, 2016). The ERA5 product also includes single high-resolution realizations at temporal and horizontal resolutions of 1 hour and 31 km, respectively. In this work, however, we only use the ensembles so that we can derive uncertainties from the members. The ECMWF has made publicly available ERA5-ensembles from 1979 up to now with a delay of within 5 days from real time (Copernicus Climate Change Service (C3S), 2017).

In the context of infrasound studies using ensemble reanalysis models, Smets *et al.* (2015) studied probabilistic infrasound propagation by performing wave-propagation simulations using the ensemble members of the ECMWF Ensemble Data Assimilation (EDA) system analysis product. Averbuch *et al.* (2020) also applied the EDA ensemble model product in atmospheric infrasound propagation modelling when analyzing how to estimate depth and strength of submerged explosion sources from infrasound data.

III. PARAMETERIZATION OF THE PROBLEM

The cost function C to optimize is represented as

$$C = \mathcal{O}(\mathbf{m}, \mathbf{d}), \quad (1)$$

where \mathbf{m} and \mathbf{d} are vectors that contain all the model parameters and observations, respectively, and \mathcal{O} is an operator. The representation in 1 is general on purpose, as this gives flexibility to incorporate different types of variable manipulations and operations within \mathcal{O} . The operator \mathcal{O} consists of:

1. Using the model parameters to produce a forecast of the observations.
2. Evaluating the cost of the model parameters by comparing the forecast with the observations using a metric of choice.

The elements of vector \mathbf{m} in our problem are the altitude of reflection of the infrasound arrival, and the profiles of temperature, zonal (W-E) and meridional (S-N) winds of an atmospheric model (vertical wind is neglected). The

vector \mathbf{d} , on the other hand, contains the observations of θ_{obs} , v^{app} and T of a corresponding Hukkakero explosion. As the source and receiver positions are fixed, this information is hard-coded inside \mathcal{O} . Consequently, the first step in our operator \mathcal{O} consists of using ray tracing with \mathbf{m} to produce a forecast of the elements of \mathbf{d} .

We compute eigenray trajectories, in this case reflection from a specified altitude joining Hukkakero with ARCES, using GeoAc (Blom and Waxler, 2012, 2017). More specifically, we use the ray tracer GeoAc3D, which considers wave propagation in a cartesian frame where the medium is moving and without resorting to the effective sound speed approximation. Then, we use the geometry from the eigenrays together with the model parameters \mathbf{m} to estimate the forecast of the observations (i.e., $\theta_{obs}^{(f)}$, $v^{app(f)}$ and $T^{(f)}$, where the superscript (f) refers to a forecast of the variable). Eigenrays are computed setting an error tolerance of 0.5° in azimuthal direction. This tolerance is within the uncertainty in the infrasound observations and results in rays landing within 0.6 km from the center of the ARCES array, which has an approximate radius of 1.5 km (Gibbons *et al.*, 2015). Notice that the actual ray tracing operates over adiabatic sound speed rather than temperature. In this work, all the model perturbations are performed over the temperature profiles and then fed into GeoAc3D, which internally converts them into adiabatic sound speed.

For the second step, we use the following cost metric:

$$\lambda = K \frac{W_1 E(\theta) + W_2 \frac{|v^{app} - v^{app(f)}|}{v^{app}} + W_3 \frac{|T - T^{(f)}|}{T}}{W_1 + W_2 + W_3}, \quad (2)$$

where

$$E(\theta) = \frac{\sqrt{\left(\sin \theta_{obs} - \sin \theta_{obs}^{(f)}\right)^2 + \left(\cos \theta_{obs} - \cos \theta_{obs}^{(f)}\right)^2}}{2}. \quad (3)$$

Equation 2 is a weighted average, which facilitates a ranking-by-priority for the fitting of the observations during the inversion. For example, observations with larger uncertainties can have smaller weights. Similarly, observations that reflect lower sensitivity to changes in the model parameters can also have lower weights. In this work, we use the weights $W_1 = 1$, $W_2 = W_3 = 3$. The smaller weight on the backazimuth is used because we observed lower sensitivity in this variable with respect to changes in the model parameters. The same behavior was reported by Vanderbeeken *et al.* (2020) in their Bayesian inversion. Traveltime and trace velocity, on the other hand, display a comparable level of sensitivity. We observed that if their weights are not equal, the algorithm often converges to solutions that fit only the variable with larger weight within its uncertainty.

The purpose of the normalizations in the fractions in the numerator of equation 2 are to remove scale differences, homogenize units, and to help ensure bounds in the cost function in the approximate range of $[0, \sim 1)$,

where the upper bound can be approached with either a greater or a smaller number. Function $E(\theta)$ is defined taking the same requirements into consideration and also to avoid ambiguities when comparing angles. In particular, setting $[0, \sim 1)$ bounds in the cost function is critical for the performance of the heuristic solver used for the optimization (Vera Rodriguez, 2019).

As we discuss in the following section, the algorithm is initialized with average profiles obtained from the members of ERA5-ensemble models. The cost of these initial atmospheric models is already small. Therefore, we prefer absolute values over the more commonly used squared differences to increase the cost of the initial models. For the same objective, we introduce the hyperparameter K . Using a value of $K = 60$ we ensure an initial cost closer to 1 in every inversion run.

A. Constraining the solution space

The inversion problem that we attempt to solve is strongly ill-posed. This is because the number of model parameters is much larger than the number of independent observations. Without access to additional observations, this limitation can be alleviated by either incorporating constraints (e.g., regularization) and/or by reducing the number of model parameters. For the first alternative, we use average profiles calculated with the members of ERA5-ensemble models as starting point. In addition, we bound the solution space to the region delimited by profiles that are a multiple of standard deviations obtained from the same ensembles. The standard deviations obtained in this way display variability with altitude, reflecting the better availability of information to constrain these models at lower altitudes. Similarly, the standard deviations for temperature are small compared to those of winds. This reflects both the better accessibility of measurements of this property in the atmosphere and its more stable nature (i.e., less variability) compared to wind.

Reducing the number of standard deviations to set the limits of the solution space has the risk of excluding solutions that best explain the infrasound data. On the other hand, extending the dimensions of the solution space increases the number and diversity of atmospheric models that can explain the observations. We find a reasonable trade-off by testing different multiples of the standard deviations to set the size of the solution space. We consider that the size of the solution space is reasonable when after running the algorithm multiple times the final solutions resemble each other and all explain the observations within their uncertainties.

Even after delimiting the boundaries of the solution space, the number of model parameters is still much larger compared to the number of observations. Thus, in order to further improve the constraint in the inversion, we simplify the ERA5-ensemble models to 1D layered versions and assume time-invariance during the propagation of the infrasound waves. Previous work suggests that these assumptions are reasonable within the dis-

tance range between Hukkakero and ARCES (e.g., Assink *et al.*, 2013; Lalande *et al.*, 2012).

For the altitude of reflection we try two different initial values. First, we run three inversions using 39 km as initialization point. This is about the average reflection altitude estimated by Blixt *et al.* (2019) for the extended dataset of explosions. After that, we run another three inversions moving the initialization point to 38 km. The purpose of trying different initial altitudes is to verify that the final solution converges toward similar values independently of the initialization point. In both cases, the solution space is bound at ± 1 km from the initial reflection altitude. This bound is determined by the distance to the position of the next closest interface in the model, so that the perturbed interface (i.e., reflecting altitude) never overlaps or moves beyond this following interface. Furthermore, the initialization interface is selected such that the final reflection altitude does not fall at the boundary of the solution space, otherwise, the inversion is reinitialized using the following interface.

There are two additional ways to improve inversion constraint, not yet implemented, but that are of interest to improve the performance of the method in the future. The first of them consists of incorporating observations from multiple phases of the wavetrain. As these phases are reflected and refracted from different locations, the lower altitude layers become better characterized. For the current tests we include only the phase with the maximum coherence in the wavetrain. The other constraint consists of acknowledging the relationship between wind and temperature. This is a physical constraint with a double benefit: on one hand, it would remove the current potential in the method to choose nonphysical solutions, and on the other, it would further simplify the solution space.

IV. INVERSION ALGORITHM

The optimization of equation 1 requires a non-linear solver. The algorithm selected here is a simplified version of the heuristic solver described in Vera Rodriguez (2019). This algorithm was designed to solve a similar problem in passive seismics, although in that case, the source locations were also an unknown and the observations to fit were waveforms (see also Vera Rodriguez, 2018; Vera Rodriguez and Le Calvez, 2018). With the simplifications, the solver approaches more the logic behind particle swarm optimization (PSO) (Shi and Eberhart, 1998), albeit with modified updating rules and contingencies to breakout from local minima.

The search for the optimization point consists in guiding a group of particles (swarm) as they explore the solution space. The coordinates of each swarm particle at any iteration are given by tentative solutions that they explore. The next exploratory move of a swarm particle is influenced by two poles of attraction: one is the best solution ever explored by that particular swarm particle and the second is the best solution ever explored by any of the particles in the swarm. This intends to simulate

the behavior of birds in their search for food sources, which is the original purpose of the PSO algorithm (Shi and Eberhart, 1998). The evaluation of what is a better solution is quantified by the cost function. This means in our application that ray tracing must be conducted at every iteration for every particle of the swarm, which makes the solver computationally expensive. The updating rules used in Vera Rodriguez (2019) improve the rate of convergence by simulating more closely the process of iterative design (Nielsen, 1993) rather than bird swarms. Additionally, we implement the solver in parallel using a workstation with 24 cores and a swarm of 96 particles. This means that, in every iteration, every core only needs to do ray tracing four times. Given the tight constraints imposed over the solution space, this was considered sufficient to identify significant and consistent minima. Unconstrained inversions in contrast require larger swarms with their particles well-spread over the solution space.

An important advantage of the heuristic solver is its flexibility, as it can optimize objective functions that are not differentiable, and permits to easily incorporate various types of constraints. The main disadvantage, on the other hand, is its computational cost, since the algorithm consists of an explicit exploration of the solution space, where success depends on a careful management of trade-offs.

Apart from simplifying the solver to handle a smaller type-set of model parameters, two other modifications were introduced. The first of them is a smoothness constraint. This constraint is applied over the temperature and wind profiles. The smoothing filter is a 79-point moving average (extending an approximate distance length of 800 m), which is applied to the signals in two directions taking care of boundary effects by padding at the ends with the end members of the profiles. Before smoothing, the profiles are resampled to a homogeneous rate computed as half of the smallest distance between layers (~ 10 m). After smoothing, the profiles are interpolated back to the original altitude points (Figure 1). This constraint is applied to every new solution to be explored by the swarm. It helps in stabilizing the ray tracing and also reduces the solution space, thus, adding robustness to the inversion process. The length of the smoothing filter is selected by trial-and-error, but it is influenced by the constraint provided by the observations. For instance, a larger number of observations to guide the inversion allows the constraint of finer structures in the model profiles, which then requires shorter smoothing filters to stabilize the inversion.

The second modification refers to the rule to accept or reject a new update for the solutions to be explored by the swarm. In PSO and the solver proposed by Vera Rodriguez (2019), an update ($\Delta \mathbf{m}$) is rejected and modified if it is larger than pre-specified, to some extent empirical, values \mathbf{v}^{max} . In our modified version, \mathbf{v}^{max} is given by the standard deviations extracted from the ERA5-ensemble and the altitude bound. The update is then rejected and modified if the updated solution ($\mathbf{m}_{k-1} + \Delta \mathbf{m}_k$, where k is the iteration number) after

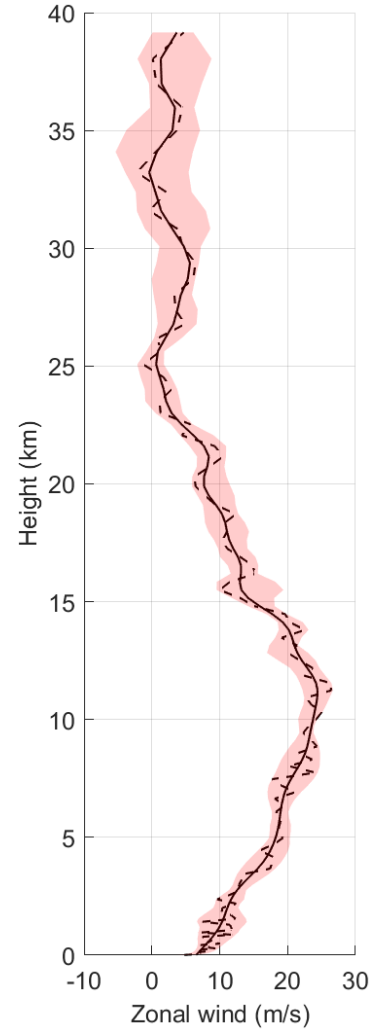

FIG. 1. Example illustrating the effect of the smoothing constraint implemented within the inversion. The oscillatory behaviour of a proposed solution (dashed line) is introduced by the pseudo-random logic of the algorithm. The smoothing filter is meant to remove these oscillations to the extent that the available observations constrain the finer structures in the profiles (solid line). The red shaded regions denote the imposed boundaries of the solution space.

smoothing is outside the limits given by the initial model and \mathbf{v}^{max} (i.e., $\mathbf{m}_0 \pm \mathbf{v}^{max}$). This is how we establish hard boundaries to the solution space (see red shaded regions in Figure 1 for an example).

For all the other hyperparameters required to run the solver, we use the values reported in Vera Rodriguez (2019). The solutions obtained with this inversion setup are temperature and wind profiles that honour the variability with altitude of the uncertainties in the ERA5-ensemble. The solutions, including reflection altitude, are also consistent with the infrasound observations and their uncertainties.

V. APPLICATION TO A HUKKAKERO EXPLOSION

We demonstrate the performance of the inversion using data from a blast on 24 August 2007 at around 11 am in Hukkakero. This example was selected at random within the catalogue of 598 explosions. Nevertheless, we observe that the inversion results are consistent with those from other explosions that we have also already analyzed (see complementary material). Figure 2 presents an example of initialization of the inversion for the selected example. The ERA5-ensemble for the time of the explosion is obtained via linear interpolation of the closest ensembles in time. The limits of the solution space for temperature and winds in this example are set as 5σ , where σ is a vector that contains the standard deviations extracted from the ERA5-ensemble. In the figure, it is visible how the uncertainty bounds increase with altitude and are also wider for winds than for temperature.

Figure 3 shows two examples of inversion results setting the limits of the solution space to 5σ . Each of the lines in the convergence plots (see Figure 3a and 3b) reflects the trajectory of a swarm particle as it finds better solutions during its exploration of the solution space. When the algorithm detects that the swarm is stuck in a local minimum (i.e., when all the convergence curves come together and do not decrease after a number of iterations) a perturbation is introduced to spread the swarm again (see Vera Rodriguez, 2019, for details). This is expressed in the convergence curves as spikes. If the breakout from the local minimum is successful the swarm continues moving. After two failures, the algorithm gives up. Therefore, the end of the convergence curves is often preceded by at least two spikes. An exception is if the algorithm finds a solution with a lower cost than a pre-specified value without getting stuck, for example, as would be the case in a convex solution space. Given the tight constraints, the variations in ray trajectories between permissible models are allowed to be only significant enough as to explain the infrasound observations (Figure 4).

From testing the inversion with different limits of the solution space, we observed that using 5σ output models that reproduced the infrasound observations well within their uncertainty limits (Table I). An illustration of the negative effects of increasing the bounds of the solution space is presented in Figure 5. In this Figure, inversion results setting the bounds to 10σ produced models that are more dissimilar between them and also with respect to the reference ensemble. On the other hand, convergence was achieved much more quickly (often within 10 iterations) because of the larger number of solutions that could explain the observations. In contrast, reducing the bounds of the solution space increased the number of iterations because the number of solutions that explain the observations becomes limited (see Table I). In our tests, 5σ provided a good trade-off to obtain solutions that resemble each other and produced forecasts within the uncertainty limits of the observations.

In these inversion results obtained with bounds at 5σ , the reflection altitude remained stable at around

38.5 km (see Table I). Convergence toward this altitude was independent of whether the initialization point was above or below. For example, the results presented in Figure 3 correspond to initialization points at 39 km and 38 km, and to runs #1 and # 6, respectively, in Table I. Both cases converged at or near this altitude of 38.5 km. Backazimuth and travel time were always better reproduced by the inverted models compared to trace velocity. This is likely related to the higher uncertainty in the estimations of trace velocity from the infrasound measurements in this dataset. Trace velocity in this example was underestimated by the ERA5-ensemble (see captions of Table I). Thus, the updates introduced by the inversion produced ray trajectories with smaller inclination angles (see Figure 4). By favouring landing trajectories with smaller inclination angles rather than simply increasing temperature and winds at the bottom of the model, the updates maintained a trade off between increasing trace velocity without negatively affecting total travel time and honouring the smoothness constraint.

Looking at the cross differences between all the inverted profiles and all the ensemble members (Figure 6), the average modifications to the ERA5-ensemble necessary to explain the infrasound observations are more significant for the wind components than for adiabatic sound speed (i.e., temperature). This is understandable, given the larger uncertainty bounds specified for the winds. Also, as a result of the variation of uncertainty with altitude, it is visible that the average differences from the ERA5-ensemble are more significant above ~ 30 km (see Figure 6d). Below this altitude the average deviations in inverted profiles from the ERA5-ensemble are within ± 0.9 m/s (i.e., ± 1.2 K) and ± 2.6 m/s, while above they lie within ± 1.7 m/s (i.e., ± 2.5 K) and ± 5.8 m/s. Another difference in the behavior of the average cross differences with respect to this altitude is their trend. In the case of adiabatic sound speed (i.e., temperature) and zonal wind, below ~ 30 km the deviations from the ERA5-ensemble oscillate around zero. Above this altitude the deviations define trends: positive deviations for zonal wind and negative deviations for adiabatic sound speed. The inversion results for meridional winds suggests a positive bias in the ERA5-ensemble with an average around 1.9 m/s along most of the profiles (see Figure 6c and d). From ~ 30 km, however, this bias shows continuous growth.

Figure 6 also highlights that the best inversion result for meridional wind (black thicker line) is not within the space spanned by the ERA5-ensemble; hence, the ensemble member that lies closer (red thicker line) plots consistently on the side of the best inversion result. For temperature and zonal wind profiles, the best inversion result oscillates more around the span of the ensemble and its closest member, although, as mentioned above, the deviations define trends at altitudes closer to the stratosphere.

Despite that systematic comparisons between lidar soundings and ECMWF products have shown differences that are often larger than those displayed in our inver-

FIG. 2. Example of inversion initialization. The initial model consists of temperature and wind profiles, and reflection altitude (black lines). The solution space is bounded with a multiple of the standard deviations of the initial model parameters (5σ in this example) and a limit manually specified in the case of the reflection altitude (red shaded areas). The search is conducted with a swarm of 96 particles whose initial position is determined by solutions (smoothed profiles) selected at random within the limits of the solution space (grey lines).

sion results (Hupe *et al.*, 2019; Le Pichon *et al.*, 2015), the ERA5-ensemble models produced reasonable initial representations of infrasound propagation over different explosion-observations in this region of north Scandinavia¹. This good representation is partly expected because most of the region where infrasound propagates in this data set falls within the part of the models where measurements are normally available for assimilation. Thus, more significant corrections derived from the proposed inversion can be expected when analyzing returns from higher atmospheric altitudes.

VI. CONCLUSIONS

We have presented an inversion scheme where complete 1D atmospheric models (i.e., temperature and wind components) can be updated with the use of infrasound observations from known sources. Furthermore, for the Hukkakero dataset that we used to demonstrate the performance of the inversion, the altitude of reflection of the infrasound waves was also an unknown that was part of the inverted model parameters.

The inverse problem is strongly ill-posed for which we had to simplify the atmospheric models to 1D, time-invariant versions. Furthermore, tight constraints were also necessary to reduce the dimensions of the solution space. We achieved this by bounding the solution space to the region around average atmospheric models obtained from ERA5-ensembles and by imposing smoothness in the solutions. Hence, the inverted/updated models explain the infrasound observations within their uncertainties and also lie in the vicinity of the ERA5-ensembles.

The inverted models displayed larger variations with respect to the reference ERA5-ensembles at stratospheric altitudes. This is consistent with a limited amount of direct measurements available to constrain the ERA5-ensembles in this region of the atmosphere. In this regard, the infrasound data becomes a valuable source of information to, at the least, point out which ensemble members should be preferred for further modelling tasks.

There are several lines to pursue in future work. For example, one possibility to modify the inversion is to weight the solutions explored by the swarm based on their proximity to a member of the ensemble. In this way, the

FIG. 3. Examples of inversion results. Each line on panels (a) and (b) tracks the convergence path of a swarm particle. The red dashed line marks the lowest misfit of any solution explored by the swarm. A spike along the convergence lines signals an attempt to breakout from a local minimum. Panel (c) shows the corresponding zonal wind profiles and reflection altitudes at each of the iterations represented in panel (a). Lighter grey colors correspond to earlier iterations. The plot also shows the initial solution (red solid line), final solution (red dashed line), and the bounds of the solution space (red shaded areas). These examples correspond to runs #1 (a) and (c), and #6 (b) in Table I.

distance between a solution and the ensemble could also be minimized. Another possibility is to incorporate additional physical constraints into the model updates. This could be attained by explicitly honoring the relationship between wind and temperature within the algorithm.

In addition, a statistical assessment of the inversion method in the context of the corresponding model ensembles could be performed based on the full multi-year dataset of hundreds of Hukkakero explosions. Ideally,

we would also prefer to confirm the inversion results using data from independent measurement technologies. It would also be interesting to compare these results to inversions found using techniques relying on orthogonal basis functions parameterized from previously determined profiles.

Moreover, extended data assimilation experiments might be initiated, building on the approaches developed by Amezcua *et al.* (2020): we could exploit that

TABLE I. Inversion results for six runs of the algorithm using 5σ to set the boundaries of the solution space. The infrasound observations are $\theta_{obs} = 175.7 \pm 0.5$ deg, $v^{app} = 337 \pm 5$ m/s and $T = 631 \pm 1$ s, and correspond to an explosion at Hukkakero from 24 August 2007 around 11 am. The forecast of the observations obtained with the average ensemble model (i.e., initial solution) is: $\theta_{obs}^{(0)} = 176.0$ deg, $v^{app(0)} = 329.1$ m/s and $T^{(0)} = 627.2$ s.

Run (#)	Iterations (#)	Cost (%)	Altitude (km)	$\theta_{obs}^{(f)}$ (deg)	$d\theta_{obs}$ (deg)	$v^{app(f)}$ ($\frac{m}{s}$)	dv^{app} ($\frac{m}{s}$)	$T^{(f)}$ (s)	dT (s)
1	121	17	38.7	175.6	0.1	334.8	2.2	631.0	0.0
2	160	16	38.2	175.7	0.0	335.1	1.9	630.8	0.2
3	104	15	38.2	175.7	0.0	335.0	2.0	631.0	0.0
4	120	18	38.7	175.7	0.0	334.6	2.4	631.0	0.0
5	112	21	38.9	175.7	0.0	334.3	2.7	631.0	0.0
6	235	16	38.5	175.7	0.0	334.9	2.1	631.0	0.0

the current inversion provides altitude-dependent, both wind components – and not only cross-winds as were assimilated in Amezcua *et al.* (2020).

Such efforts are targeting as a long-term objective to let infrasound datasets contribute to numerical weather prediction models and an enhanced medium-range forecasting that takes further advantage of the predictive skills provided by a more reliable representation of stratospheric dynamics in models.

Finally, another line of future work consists of extending the data input to the inversion process by including travel-time, backazimuth, and apparent velocity estimates related to the full stratospheric arrival wave-train, and not only a single data point associated with maximum array coherence. For higher-top models, we could also include mesospheric or lower thermospheric arrivals, hence both allowing layers at higher altitudes to be updated and also simultaneously improving the model constraints for lower altitudes.

ACKNOWLEDGMENTS

We thank two anonymous reviewers for critical reading and constructive comments which helped us improve and clarify this manuscript. The ERA5 ensemble data were accessed from the ECMWF MARS archive using the Climate Data Store API (Copernicus Climate Change Service (C3S), 2017). The infrasound waveforms used in this work were recorded at a primary seismic station which is part of the International Monitoring System (Dahlman *et al.*, 2009). These data can be requested for academic purposes from the CTBTO International Data Centre (IDC) in Vienna using the virtual Data Exploration Centre (vDEC).

We are grateful to the Seismoacoustics group at Los Alamos National Laboratory for making the ray tracer GeoAc publicly available through GitHub at <https://github.com/LANL-Seismoacoustics/GeoAc>.
