

A night-side shock aurora and its three different  
emissions observed on 26 February 2023

**Key Points:**

- Three types of shock aurora, instead of two, are observed at 21 MLT by ground-based cameras.
- They most likely correspond to three different geomagnetic signatures of an SC: DL, PI, and MI.
- The propagation speeds of the current and aurora can be different for the MI signature.

**Abstract**

Ground-based observations of shock aurora, which is an aurora related to geomagnetic sudden commencement (SC), have mainly been limited to the dayside. On 26 February 2023, right after the SC onset at 19:24 UT, ground-based all-sky cameras and a wide-angle camera detected shock aurora at 21 MLT in the auroral zone. For this aurora, three different emissions are detected instead of the previously known two emissions: intensification of a pre-existing arc (19:25 UT), red diffuse aurora (19:28 UT), and a second, green discrete arc (19:31 UT). The relative location of these emissions differs from the dayside cases where the first and last types are not distinguished. Geomagnetic data under this aurora indicates a significant difference in the anti-sunward propagation velocity between the secondary discrete arc and the related field-aligned current.

**Plain Language Summary**

Ground-based observations of “shock aurora” related to “sudden commencement (SC),” which is a sudden geomagnetic activity caused by a rapid increase of the solar wind speed (such as caused by a solar storm), were previously limited to the dayside. However, the recent development of dense networks of auroral cameras and magnetometers allows us to examine the shock aurora in the nightside from the ground. On 26 February 2023, shortly after the onset of an SC at 19:24 UT, ground-based all-sky cameras and a wide-angle camera detected the shock aurora at 21 MLT in the auroral zone. Three distinct optical emissions, instead of the two emissions previously observed on the dayside, appeared with clear time delay and locational difference: intensification of a pre-existing arc (19:25 UT), red diffuse aurora (19:28 UT), and a secondary green discrete aurora (19:31 UT). There are also other differences from dayside observations: the last emission had a different propagation speed than the related field-aligned current, and the relative location of the three emissions was different.

**1 Introduction**

Geomagnetic sudden commencement (SC), which is caused by a rapid increase in solar wind dynamic pressure, consists of a stepwise increase and subsequent bipolar spike in the geomagnetic field (Araki, 1994, and references therein). These Disturbances are the most outstanding ground magnetic field perturbation at Low latitudes and the Polar region, hence called DL and DP, respectively. DP is normally divided into two parts, the preliminary pulse, PI, and the main pulse, MI. Following the model of Araki (1994), PI is associated with a field-aligned current (FAC) pair flowing into the afternoon auroral zone and out of the morning auroral zone while traveling anti-sunward. PI is replaced by the MI some minutes later which is a stationary FAC pair of opposite directions compared to the PI pair.

Both disturbances are ultimately caused by an intensification of the magnetopause current, of which the information propagates globally across the geomagnetic field as the compression (this causes the DL on the ground) and as the Alfvén mode that carries FACs along the geomagnetic field, creating dusk-to-dawn and dawn-to-dusk ionospheric electric field and relevant current system (this causes the DP on the ground). Hence, the DL appears almost simultaneously (less than tens of seconds) at all magnetic local time (MLT) regions. DP (actually the PI part) also appears nearly simultaneously at all latitudes, although it is related to a current system that takes time to develop. This is because the related electric field in the ionosphere can propagate almost instantaneously as a waveguide mode (Kikuchi, 2014).

Measuring the time delay from dayside to nightside is difficult because the beginning signature of MI is hidden by the DL (and even PI). Even the peak timing is not well determined because the duration and peak timing of the MI in the polar cap (anti-sunward convection side) depends on latitudes (Araki & Allen, 1982). One method for estimating the propagation velocity of the MI is to measure the optical aurora, which is typically colocated with the intensification of FACs. The optical aurora related to an SC is actually observed by ground-based all-sky cameras (ASCs) and ultraviolet (UV) imagers onboard satellites (Kozlovsky et al., 2005; Liu et al., 2011), and is called shock aurora. Motoba et al. (2009) examined a shock aurora at 15 MLT and identified both the PI-related diffuse patch (558 nm: green) equatorward of a pre-existing arc and the MI-related discrete arc (558 nm and 630 nm: red) poleward the PI-related diffuse aurora. The relative location of the MI-related arc and pre-existing arc changes with the interplanetary magnetic field (IMF) and may overlap with each other (seen as an enhanced oval) for the northward IMF (Nishimura et al., 2016).

Nishimura et al. (2016) also obtained the spatial distribution of FACs and their temporal development using the magnetometer network in the northern hemisphere and compared it with images from ASC in Antarctica. The result suggests that the PI and MI correspond to diffuse and discrete auroras in the afternoon sector, respectively. Since the optical signature of the aurora provides a finer FAC structure than what a network of geomagnetic field measurements can provide, observation by cameras is necessary to reveal the detail of the SC current system. The method should have been applied to the nightside, but the only report from the ground-based optical measurements is by meridian scanning photometers (Holmes et al., 2014). Without such optical observations, we do not know how the FAC develops as it propagates to the nightside or even whether the aurora types are the same between day-side and nightside.

According to the global imaging from satellites, the MI(PI)-related electron aurora propagates anti-sunward at about 4–6 km/s (10 km/s) on the duskside (dawn-side) ionosphere (Zhou & Tsurutani, 1999; Holmes et al., 2014), and the shock aurora can extend to the midnight sector. Using multiple scanning photometers, which are separately installed by about 1100 km in the evening sector and 900 km in the morning sector, Holmes et al. (2014) demonstrated that the anti-sunward propagation speed is consistent with the result from satellite observations. The derived speed in the evening sector corresponds to 1–1.5 MLT/min, requiring 8 min from dayside to nightside (20–22 MLT), consistent with the start of the MI signature 6 min after the SC onset. On the other hand, Holmes et al. (2014) detected the red (630 nm) emission 1 minute before the appearance of the green (558 nm) aurora, which indicates that low-energy electrons may have precipitated into the ionosphere 3 min prior to the high-energy ( $> 1$  keV) electrons if we take into account the average relaxation time of the red aurora of about 2 min. The FAC corresponding to the duskside red aurora must have arrived much earlier than the source FAC for the green aurora in Holmes et al. (2014), giving a quite different anti-sunward propagation speed between the source of the red aurora and that of the green aurora.

To summarize our understanding so far, there are two types of shock aurora in addition to pre-existing arc: the PI-related and MI-related auroras, and they might have different propagation speeds from each other. If so, the difference in the appearance time of these auroras would be larger on the nightside than on the day-side. In addition, the relative location of these auroras and even the fine structure might also be different between dayside and nightside. To clearly distinguish these auroras and their temporal development on the nightside, we need observations of multi-wavelength cameras and a dense meridional network of the magnetometer in the auroral region.

On 26 February 2023, right after an SC onset at 19:24 UT, a color ASC in Kiruna that was located at 21 MLT ( $65^{\circ}$  geomagnetic latitude) detected (1) the enhancement of a pre-existing green arc (19:25 UT), (2) the appearance of a red diffuse aurora (19:28 UT), and (3) a secondary green arc (19:31 UT) at unexpected location (equatorward of the pre-existing arc), with the geomagnetic MI peak at 19:27 UT. We also observed the secondary arc with a high-time resolution wide-angle camera, which revealed the vortex motion of the arc. The shock aurora was weakened within 20 min, and this interval was isolated from the subsequent substorm growth phase. The shock aurora appeared above the densely distributed magnetometer network (IMAGE), and the relative location of FACs and aurora can be derived in good resolution. Here we report these combined observations of the shock aurora seen 3 hours before the magnetic midnight.

## 2 Instruments

### 2.1 All-sky cameras (ASCs)

We analyzed all-sky images from cameras in Kiruna, Sweden ( $67.83^{\circ}\text{N}$ ,  $20.42^{\circ}\text{E}$ ) and Skibotn, Norway ( $69.35^{\circ}\text{N}$ ,  $20.36^{\circ}\text{E}$ ). In Kiruna, a Sony  $\alpha$ 7S with a Nikkor 8mm F2.8 lens was installed. The camera's ISO was set at 4000, and the exposure time was 10–13 sec. Images were taken every minute. At Skibotn Observatory, a Sony  $\alpha$ 6400 with a MEIKE MK-6.5mm F2.0 lens was in operation. The camera's ISO was set at 8000, and the exposure time was 8 sec. Images were taken every 30 sec. We used these images to geolocate and identify spatiotemporal variations of the aurora.

### 2.2 Wide-angle camera (WAC)

A Sony  $\alpha$ 7SIII with an FE 24mm F1.4 GM lens was installed at a dome where the Kiruna ASC was located. This camera, called wide-angle camera (WAC), faces in the north-northeast direction at a low elevation with an angle of view of  $\sim 73$  degrees horizontally, covering an area marked by a white rectangle in the last panel of Figure 2. WAC recorded videos at 30 frames per second, offering a high temporal resolution for visualizing auroral movement within 1 minute. WAC has  $1920 \times 1080$  pixels, an ISO sensitivity of 80000, and a 1/30 second exposure time. We averaged 15 images (for 0.5 seconds) to make snapshots to reduce noise, as shown in Figure 3. We provide a video of the event as Supporting Information.

### 2.3 Magnetometers

A selection of magnetometers from the IMAGE network has been applied in the study. These are stable flux-gate magnetometers, providing 10-second resolution data. Furthermore, the low latitude, Intermagnet magnetometer at Huancayo has been used.

## 3 Observation Results

Figures 1a and 1b shows the IMF (intensity in black and the  $z$  component in red) and solar wind dynamic pressure, respectively, from the Deep Space Climate Observatory (DSCOVR). A stepwise enhancement of the IMF intensity and dynamic pressure, a typical signature of the interplanetary shock, was detected at around 18:40 UT. Figure 1c shows the  $H$  component of the geomagnetic field recorded by magnetometers located in Sørøya (SOR), Norway ( $70.54^{\circ}\text{N}$ ,  $22.22^{\circ}\text{E}$ ); Tromsø (TRO), Norway ( $69.66^{\circ}\text{N}$ ,  $18.94^{\circ}\text{E}$ ); Kilpisjärvi (KIL), Finland ( $69.02^{\circ}\text{N}$ ,  $20.79^{\circ}\text{E}$ ); Kiruna (KIR), Sweden ( $67.83^{\circ}\text{N}$ ,  $20.42^{\circ}\text{E}$ ); and Huancayo (HUA), Peru ( $12.06^{\circ}\text{S}$ ,  $75.21^{\circ}\text{W}$ ). Their locations, except HUA, are shown in Figure 1g. HUA is instead located on the

163 dayside equator at  $\sim$ 14.2 MLT, which is the typical SC onset region. All the sta-  
 164 tions show the SC signature starting at around 19:24 UT. This SC is isolated from  
 165 the substorm activity that started around 20:20 UT, and hence we show only the  
 166 short time interval in Figure 1e (19:21–19:32 UT). The onset time ( $\sim$  19:24:00 UT)  
 167 is marked by a dashed line (left). Similarly, the peak time of the PI ( $\sim$  19:25:20 UT)  
 168 is also marked by another dashed line (right).

169 Figures 1d and 1f show the keogram, the time series of the north-south cross-  
 170 section of the all-sky images from Kiruna ASC. Note that the exposure time changed  
 171 from 10 to 13 sec at 19:28 UT. The keogram shows that the aurora appeared shortly  
 172 ( $\sim$ 15 min) after the SC, and its intensity gradually increased for the first  $\sim$ 10 min.  
 173 Figure 1f shows a time lag between the magnetic signatures and the auroral inten-  
 174 sification.

175 In Figure 1g, all-sky images obtained by the ASCs in Kiruna and Skibotn at  
 176 19:33 UT are projected on the map showing the locations of the magnetic stations  
 177 and cameras. Coordinates with an elevation angle of more than 20 degrees were  
 178 used for the projection, and the auroral emission layer was assumed to be 100 km.  
 179 The projected aurora is found close to the zenith of Kilpisjärvi and Tromsø ( $67.5^\circ$   
 180 MLAT, 21 MLT).

181 Figure 2 is a minute-by-minute all-sky image from 19:23 to 19:34 UT. The up-  
 182 per side of each image is north, and the left side is east. The solid white line in the  
 183 first panel shows the cross-section used to make keograms shown in Figure 1. The  
 184 first all-sky image at 19:23 UT, taken before the SC onset, already shows a weak  
 185 diffuse aurora (circled by the white dashed line) in the northeast direction. In this  
 186 paper, we refer to this aurora as the pre-existing arc. The third all-sky image was  
 187 taken 1 minute after the onset and shows that the arc is stronger than before the on-  
 188 set, as indicated by the yellow arrow. At 19:28 UT, as indicated by the red arrow,  
 189 a red emission became visible south of the pre-existing arc that was further intensi-  
 190 fied. This intensification causes the automatic change in the exposure time from 13  
 191 to 10 sec. At 19:31 UT, discrete arcs with wavy structures were detected between  
 192 the pre-existing arc and the red emission at both the west (right) and east (left)  
 193 sides. They were connected at 19:32 UT and formed an arc from west to east, and  
 194 the wavy structure became stronger afterward. In this paper, we refer to this arc  
 195 as the secondary arc. The last four all-sky images (19:31–19:34 UT) show the quick  
 196 evolution of the secondary arc every minute. The 1-min resolution is apparently too  
 197 low to visualize the exact fine spatiotemporal evolution of the secondary arc. For-  
 198 tunately, we have a 30 Hz video taken by WAC. WAC captured the white rectangle  
 199 region in the last all-sky image in Figure 2.

200 Figure 3 shows the images taken by WAC observing the area shown in the last  
 201 panel of Figure 2. The images obtained from 19:34.12.1 to 19:35:08.1 UT are shown  
 202 every 8 seconds. In the electronic version of this paper, a real-time video of this se-  
 203 quence is provided as Supporting Information. Note that the east-west direction of  
 204 the image is reversed from the all-sky image. The meridian with an azimuth angle of  
 205 0 degrees (northward) is shown as a dotted line in panel (a). In each snapshot, two  
 206 auroral structures are visible with a spatial gap near the center of the image. Both  
 207 wavy structures gradually steepened by the westward motion on the front side (low  
 208 latitude side) and eastward motion on the back side (high latitude side), as indicated  
 209 by the white arrows. As this steepening developed, these structures consequently  
 210 formed a spiral shape.

## 211 4 Discussion

212 The shock aurora was observed by ASCs and the high-speed WAC in the evening  
 213 sector at around 21 MLT. Three components of shock aurora were identified instead  
 214 of only two (PI-related diffuse aurora and MI-related arc), which was the case for  
 215 the dayside afternoon sector. Their characteristics are summarized in Figure 4, in  
 216 which the locations of the aurora are illustrated in the polar view.

- 217 1. Pre-existing weak arc (green, most likely 558 nm) was gradually intensified  
     right after the SC onset at 19:24 UT.
- 218 2. Red diffuse aurora (apparently 630 nm) gradually appeared widely in the lon-  
     219 gitudinal direction equatorward of the intensified pre-existing arc, as shown in  
     220 Figure 4a. This aurora became visible at 19:28 UT, i.e., 4 min after the onset.
- 221 3. Discrete green (secondary) arcs suddenly appeared between the red diffuse  
     222 aurora and the intensified pre-existing arc at two separated spots (west and  
     223 east in the WAC images). They became visible at 19:31 UT (7 min after the  
     224 SC onset) and developed before start moving.

226 We also examined a video from the EMCCD ASC in Tjautjas, Sweden (at-  
 227 tached as Supplemental Information), and found that the western and eastern arcs  
 228 seen at 19:31 UT in Figure 2 appeared at around 19:30:52 and 19:31:12 UT, respec-  
 229 tively. Both arcs did not propagate gradually but appeared as jump as independent  
 230 clumps. The jumping speed from west to east (about 0.5 MLT apart) is about 1.5  
 231 MLT/min. After the appearance, both arcs started expanding in the east-west di-  
 232 rection (Figure 4b) and got connected to each other. Subsequently, they showed  
 233 the vortex motion without changing their locations, as shown in Figure 4c. The sec-  
 234 ondary arc might be accompanied by the red emission (most likely 630 nm) at high  
 235 latitudes, but it is difficult to examine the continuity from the ASC images.

236 Considering the average relaxation time of  $\sim$ 2 min for the red diffuse aurora,  
 237 the precipitation of the low-energy electrons might have started only 1–2 min after  
 238 the SC onset. In the evening sector, diffuse auroras are generally associated with  
 239 downward FAC, whereas intensified arcs are generally associated with upward FAC  
 240 (e.g., Marklund et al., 2011). Therefore, the pre-existing arc (upward FAC) and red  
 241 diffuse aurora (downward FAC) may be related to the DL and PI, respectively. In  
 242 other words, the DL might also have generated the shock aurora by intensifying the  
 243 pre-existing arc for the present case. If so, the past dayside observation of the MI-  
 244 related aurora might be contaminated by the DL-related aurora.

245 The time delay of the appearance of the secondary arc from the SC onset was  
 246 7 min (and 5–6 min from the MI onset); thus, the anti-sunward propagation speed  
 247 from the noon sector is about 1.5 MLT/min. This value is similar to the propa-  
 248 gation/expansion speed of the MI-related arc in the afternoon sector (Motoba et  
 249 al., 2009; Holmes et al., 2014; Nishimura et al., 2016). The nightside propagation  
 250 speed estimated by the jumping of the secondary arc was also similar, about 1.5  
 251 MLT/min. Such an agreement indicates that the propagation of the MI-related au-  
 252 rora may be in the form of a leap rather than a continuous extension.

253 The secondary arc was located equatorward of the intensified pre-existing arc  
 254 and overlapped with the red diffuse aurora, indicating that the source electric field  
 255 existed at an L-shell in the middle of the ring current region. This implies that the  
 256 affected areas in the nightside magnetosphere by the DL, PI, and MI are not in the  
 257 same latitudinal order as the dayside signature in terms of the L-shell. This is not  
 258 impossible if we consider the difference in the propagation velocities of the DL (com-  
 259 pression) and DP (Alfvénic). If the relative latitude of the aurora is reversed be-  
 260 tween dayside and nightside, we must interpret the result from the meridian scan-

261 ning photometer (e.g., Holmes et al., 2014) in a different manner between dayside  
 262 and nightside.

263 The present result also provides new insight into the anti-sunward propagation  
 264 speed of the FAC structure. Since the approximate FAC intensity is calculated  
 265 from the latitudinal gradients of the H component of the geomagnetic field from  
 266 the ground, the peak of FAC intensity read from Figure 1e (SOR, TRO, KIL, and  
 267 KIR) is at 19:27 UT, i.e., 3 min after the SC onset at 19:24 UT. If we consider the  
 268 start time of this gradient, the FAC already intensified at 19:26 UT, only 2 min after  
 269 the SC onset. This means that the FAC propagated from dayside to 21 MLT with  
 270 a speed of at least 4 MLT/min. This is much faster than the propagation speed of  
 271 the MI-related aurora (1.5 MLT/min). Then the question is why the time delay be-  
 272 tween the FAC and aurora intensification increases as it propagates anti-sunward.  
 273 This question remains for future investigation.

274 Figures 3 and 4c show that the auroral vortex develops nearly stationary, sug-  
 275 gesting that the anti-sunward convection poleward of the arc and sunward convec-  
 276 tion equatorward of the arc have similar speeds. Such stationarity raises a ques-  
 277 tion on the convection: how does the convection develop as the SC signature and  
 278 shock aurora propagate anti-sunward? Together with the leap-like appearance, the  
 279 formation of the aurora and its relation to the current system needs future investi-  
 280 gations. Fortunately, modern optical instruments are rapidly improving their sen-  
 281 sitivity, and the number of optical stations is increasing. Furthermore, the incom-  
 282 ing SMILE (Solar wind Magnetosphere Ionosphere Link Explorer) mission to be  
 283 launched in 2024–2025 would give a long-time global UV monitor from almost the  
 284 same location. Combining its image with improved ground-based optical ability will  
 285 allow systematic studies of the shock aurora on the nightside.

## 286 5 Conclusion

287 We observed the nightside shock aurora with ground-based all-sky cameras and  
 288 a high-speed wide-angle camera at 21 MLT. Unlike the dayside shock aurora, where  
 289 only two types of (PI- and MI-related) emissions are reported, we identified three  
 290 emissions: enhancement of the pre-existing arc, the red diffuse aurora, and the dis-  
 291 crete arc. These emissions most likely correspond to three different geomagnetic sig-  
 292 natures of an SC: DL, PI, and MI. We believe that this is the first time observation  
 293 of DL-related emission. For the MI signature, the anti-sunward propagation speed of  
 294 the field-aligned current seems to be much faster than that of the related aurora. In  
 295 addition, the relative location of the MI-related aurora and intensified pre-existing  
 296 arc is not necessarily the same between the dayside and nightside.

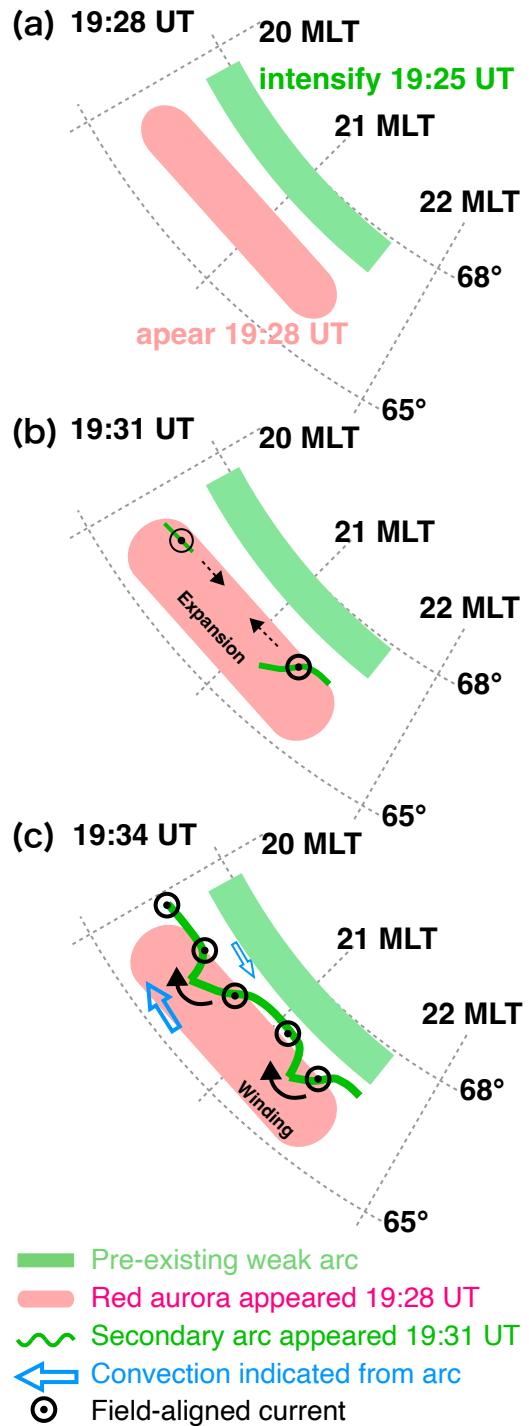

**Figure 1.** (a–b) The intensity (black) and  $z$  component (red) of the interplanetary magnetic field and solar wind dynamic pressure from DSCOVR. (c) Magnetometer data from the stations in the auroral and equatorial regions. A scale of 100 nT is shown in the lower left. (d) North-to-south keogram from the Kiruna ASC. (e–f) Close-up views of panels (c) and (d) from 19:21 to 19:32 UT. Vertical dashed lines indicate the onset of the SC and peak time of the PI. (g) Projection of all-sky images from the Kiruna and Skibotn ASCs. The location of the magnetometers is also shown. The grid line gives the magnetic local time and latitude.

**Figure 2.** The ASC images from Kiruna during 19:23–19:34 UT on 26 February 2023. The top is north, and the left is east. The white dashed region in the first panel shows the pre-existing arc. The appearance of the red aurora and secondary arc is marked by red and blue arrows, respectively. The white rectangle region in the last panel is the FoV of the images shown in Figure 3.

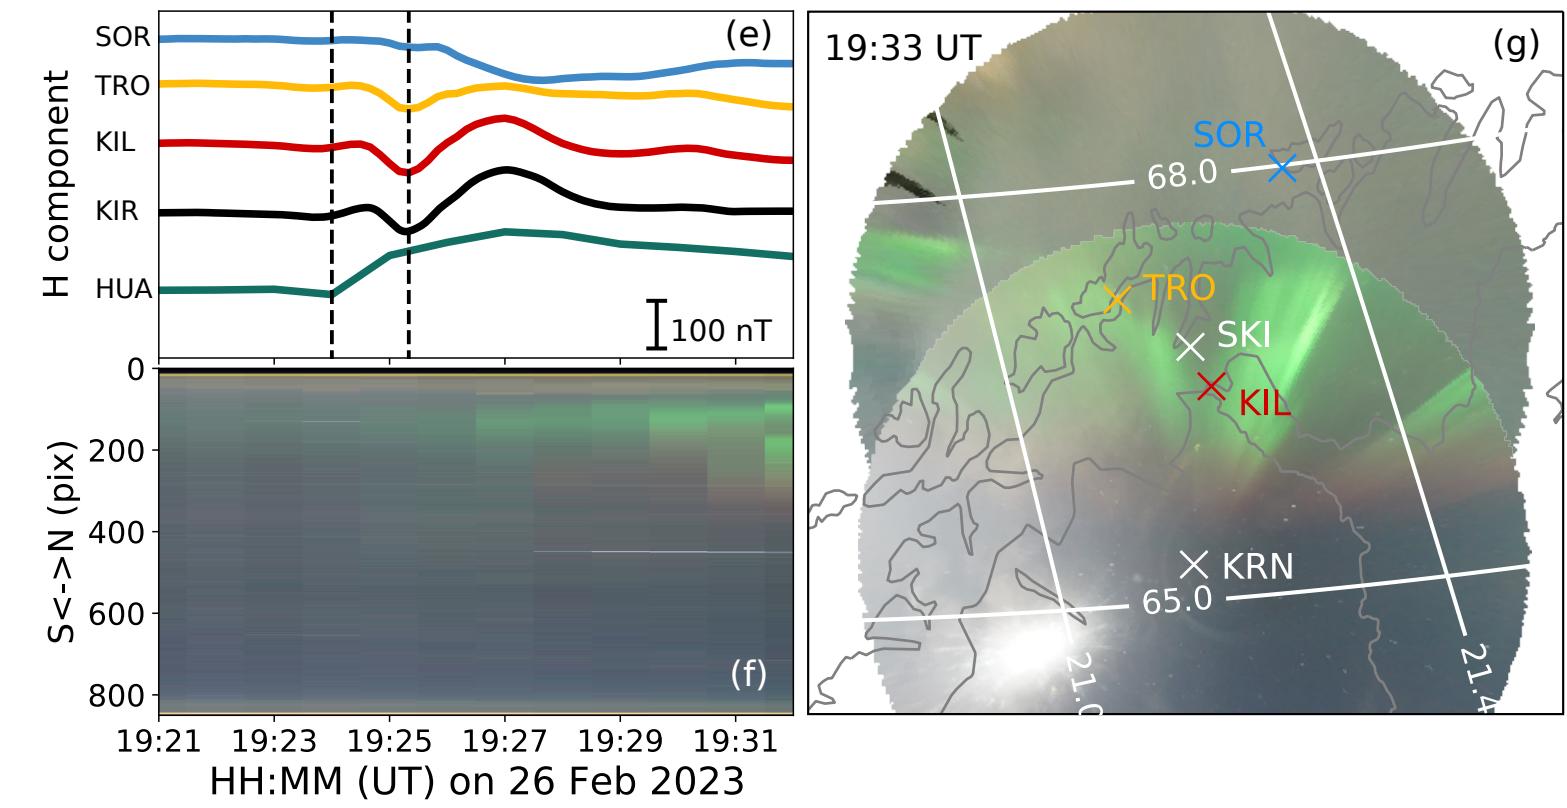

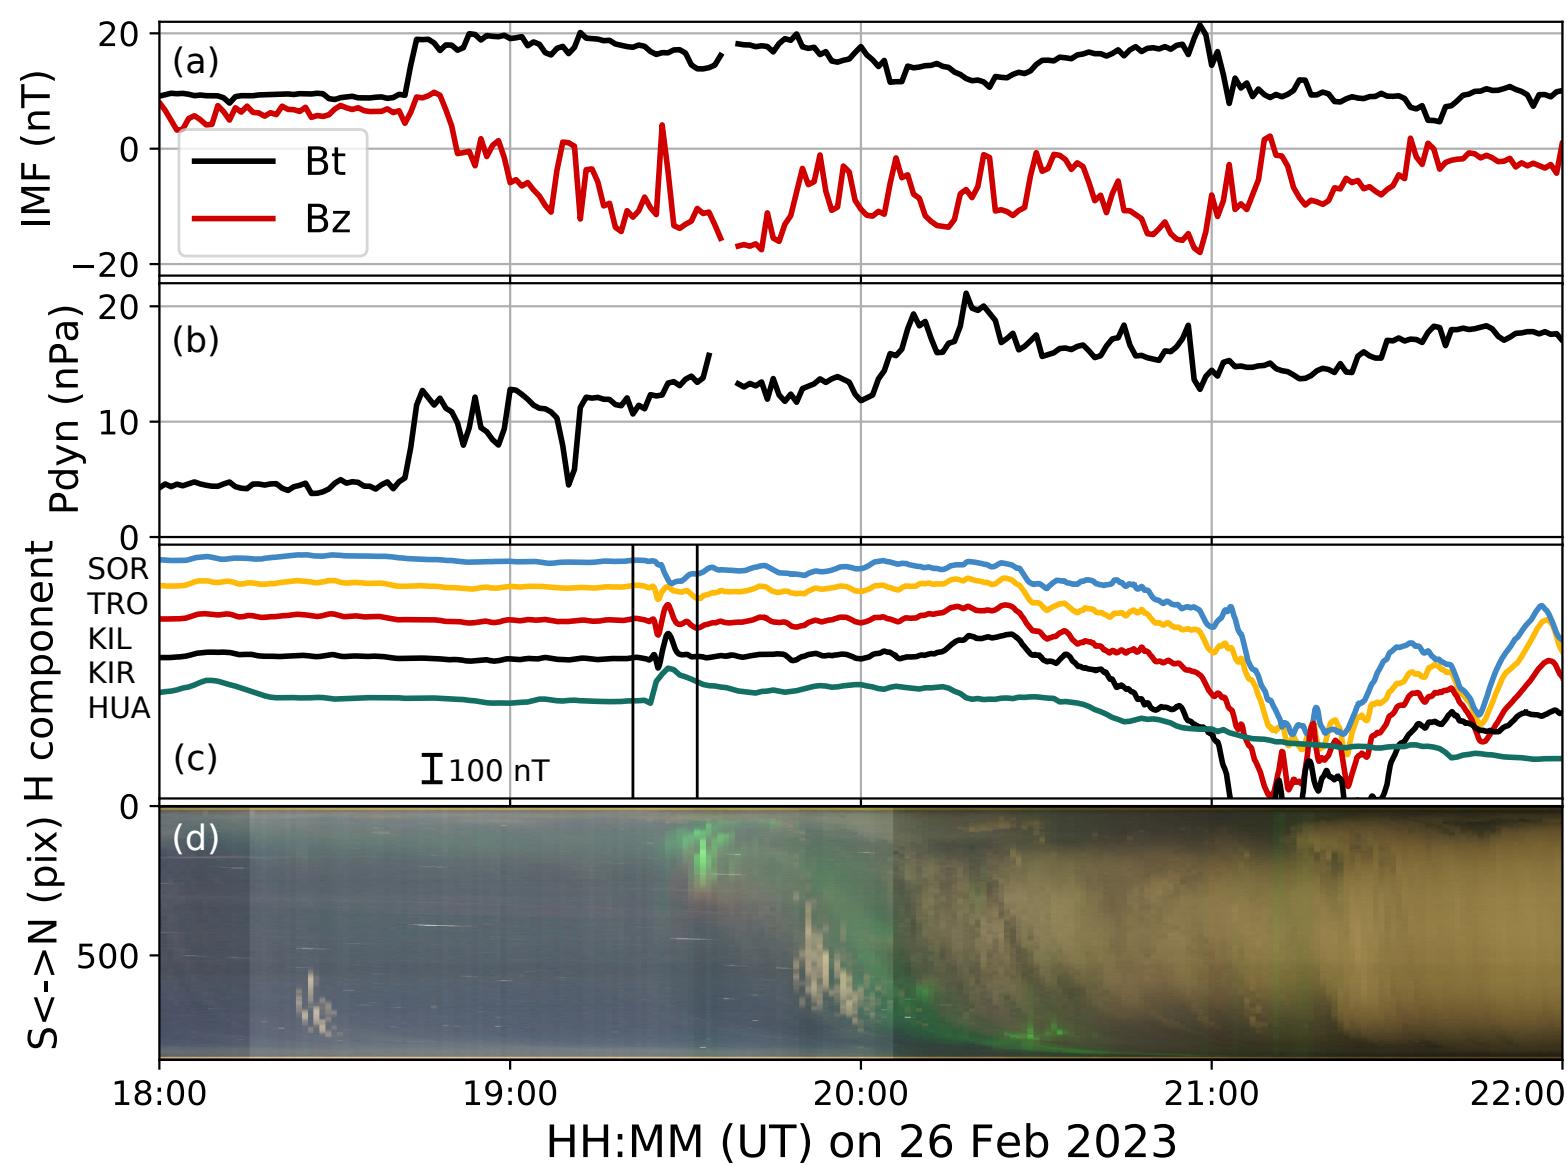

**Figure 3.** The wide-angle images captured by the Sony α7SIII camera during 19:34:12–19:35:08 UT. The right side is east (different from the ASC image). The white dashed line in the first panel indicates the meridian, which has an azimuth angle of 0 degrees (towards the north). The white arrows guide the vortex motion.

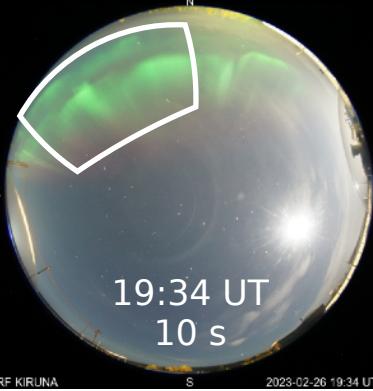

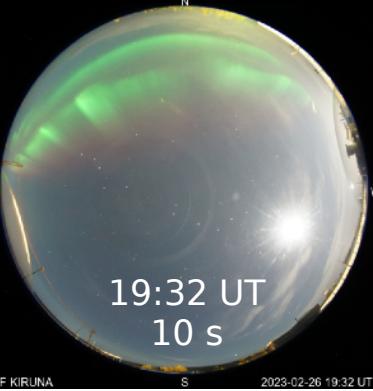

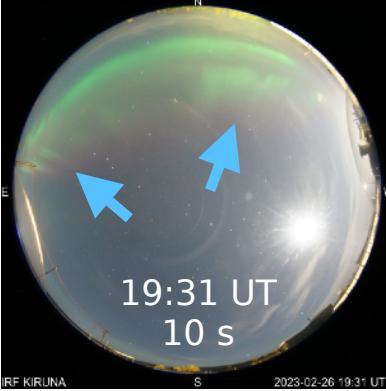

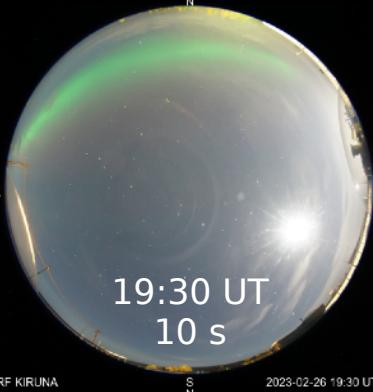

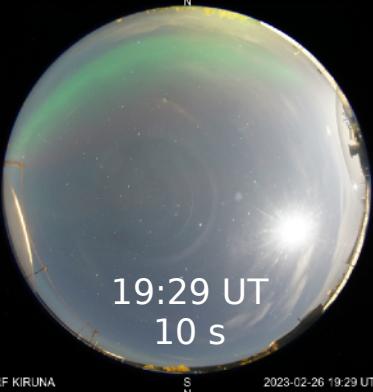

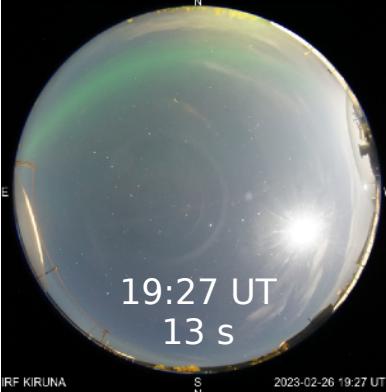

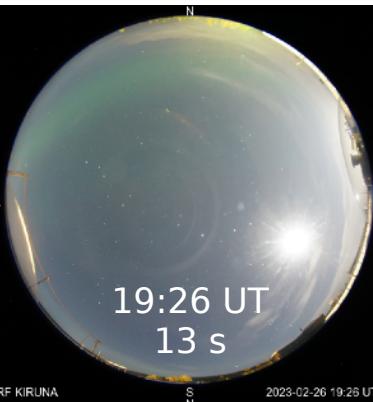

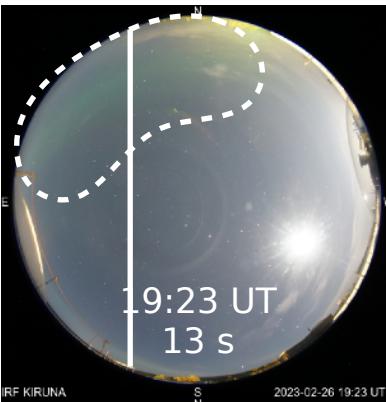

**Figure 4.** Schematic illustration of the relative locations of pre-existing arc, red diffuse aurora, and secondary arc. The blue arrows indicate the convection directions suggested by the vortex motion of the secondary arc.
