Abstract

Carbonyl sulfide (OCS) is used to quantify the carbon capture potential of the biosphere because of its direct correlation with CO_2 uptake during photosynthesis. However, to constrain the urban biosphere signal, it is necessary to evaluate potential anthropogenic sources. We conducted two sampling campaigns in the Metropolitan Area of Barcelona (AMB), Spain, during May (full COVID lockdown) and October 2020 to measure the spatial distribution and variability of OCS in four urban land uses as follows: built, urban forest, urban park, and peri-urban agriculture. The OCS background levels determined at Tibidabo (442 m asl) were approximately 484 ±20 ppt and 407 ±8 ppt for May and October 2020, respectively, and

agreed with other seasonal surveys conducted in Europe during that same period. The urban values ranged from neutral to above background, suggesting nearby anthropogenic and marine emissions such as +Δ150 ppt in Montjuic, which is downwind of Barcelona's harbor. During the crop-growing season in May, the agricultural areas consistently showed values below the background (uptake) at 7:00 UTC when the land breezes were dominant, while later in the morning, when the sea breeze are developed, the plant sink is masked by the transport of marine emissions. Urban forests located north of Tibidabo showed OCS values up to -Δ70 ppt, suggesting significant uptake by urban forests. We conclude that determining the urban biosphere signal using OCS as a tracer is more complex than expected because the marine and anthropogenic emissions from the port strongly impact the spatial-temporal distribution of OCS.

Introduction

Carbonyl sulfide (hereafter OCS) is an atmospheric trace gas used to study the CO_2 sequestration capacity of vegetation (Remaud et al., 2023 and references therein; Whelan et al., 2018 and references therein) because it is destroyed through photosynthesis in the same way as CO_2 without producing any emissions through respiration (Protoschill-Krebs and Kesselmeier, 1992). According to the latest estimations, terrestrial vegetation and soils takes up from 530 and 670 Gg S yr^{-1} (Remaud et al., 2023 and references therein) the largest natural sink of atmospheric OCS. Surface oceans are the most important natural source of OCS contributing directly and indirectly, i.e., from the atmospheric oxidation of carbon disulfide and dimethylsulfide, between 270 and 320 (Remaud et al., 2023 and references therein). The global budget of OCS is partially balanced by anthropogenic emissions, which are estimated to be 400 Gg S yr^{-1} (Remaud et al., 2023 and references therein). Terrestrial sinks and natural and anthropogenic sources are generally separated in space and time, and exhibit distinct seasonal

and spatial variations (Remaud et al., 2023). Hence, land use changes are expected to have a significant influence on the global budget of atmospheric OCS.

Although many studies have evaluated OCS budgets at regional and global scales, little is known about OCS sources and sinks at the urban scale. Understanding land use influence on the budget of atmospheric OCS at the urban scale is much more difficult to establish because sources and sinks can coexist over small distances. For example, Commane et al. (2013) indirectly assessed OCS sources along the highly urbanized coastline of California where they detected biogenic OCS emissions from wetlands in Sacramento Bay, anthropogenic emissions near a storage facility and refinery in the port of Los Angeles, and OCS loss during the daytime due to photosynthetic uptake in vegetated areas. Besis et al. (2021) also conducted a study that identified potential sources of OCS at the city level and observed the spatial heterogeneity influencing OCS mixing ratios of Thessaloniki, Greece, and identified three locations where OCS concentrations in inner-city areas were three times higher than those at the seafront and where the waste management system was a source of OCS. According to Zumkehr et al. (2018), anthropogenic emissions of OCS due to aluminum, residential and industrial coal, TiO_2, solvents and tires in the Metropolitan Area of Barcelona contribute to 65% (178 Mg S yr^{-1}) of the total emissions in the Catalonia region (276 Mg S yr^{-1}, see Fig. S1 in supporting information). However, a study by Belviso et al. (2023) demonstrated that the Zumkehr et al. (2018) inventory for France largely overestimated OCS anthropogenic emissions by approximately an order of magnitude. A previous study by the same group used direct measurements from a sampling tower and computed back trajectories with the FLEXPART transport model to find that the Paris suburban area was acting mainly as an OCS sink (Belviso et al., 2022). Another urban study of Innsbruck, Austria, measured the hourly exchange rates of OCS with an eddy covariance tower and showed that urban OCS emissions are significantly higher at noon during weekdays than during weekends, which suggests that road traffic could be a net source of OCS emissions.

The use of OCS as a photosynthesis tracer has recently received attention as a potential method to determine the contribution of the urban biosphere toward reducing the carbon footprint (Mallik et al., 2016; Villalba et al., 2021). Mallik et al. (2016) reported the first records of annual OCS mixing ratios over an Indian city, which were substantially higher than tropospheric values, and those values changed seasonally with an observed 86% drop in OCS in November when air masses changed from oceanic to continental. Villalba et al. (2021) also observed changes in OCS related to air masses coming from marine and continental sources. This work highlighted the difficulty of characterizing the biosphere signal when the input masses are continental due to the heterogeneity they present in OCS content compared to stable marine conditions.

This study aims to contribute to the understanding of the dynamics of OCS budgets in urban areas by exploring to what extent different urban land uses can have an impact on atmospheric OCS mixing ratios in terms of the particular urban climate, geography, and topography affecting the transport and mixing of OCS sources and sinks. Motivated by the present lack of in situ OCS continuous measurements to properly infer surface OCS (Remaud et al., 2022), we conducted an OCS measurement campaign in the Metropolitan Area of Barcelona (AMB). We selected four different land uses as sampling sites as follows: forest, agricultural land, urban parks and impervious areas with the intention of understanding the role of urban land use on the OCS budget in a coastal city where we would expect a mixing ratio gradient between the sea (where OCS is produced) and the land (OCS capture in vegetated areas). The selection of sampling areas was based on their potential as a sink of OCS based on photosynthetic rates (Campbell et al., 2017; Villalba et al., 2021; Yang et al., 2018) or a local source based on anthropogenic inventories (Lee and Brimblecombe, 2016; Yan et al., 2019; Zumkehr et al., 2018). The OCS sampling campaigns were funded and conducted within the project *Integrated System Analysis of Urban Vegetation and Agriculture* (URBAG), which was financed by the European Research Council with the overall aim of understanding the

influence of green infrastructures on the urban CO_2 budget. As a coastal city with intense sea breezes during the day, the AMB is an ideal case study to determine the contribution of the urban biosphere and other anthropogenic sources to the overall urban OCS budget. The campaigns were conducted during the spring and early autumn of 2020 and almost coincided with the OCS spring maximum and autumn minimum (Montzka et al., 2007). Furthermore, the May campaign took place during the full lockdown due to the COVID pandemic, which helped constrain the biosphere signal given the reduction in anthropogenic activities that are potential sources of OCS such as vehicle exhaust (Zumkehr et al., 2017). We analyzed the observed OCS concentrations in terms of land-use influence while understanding the role of local weather conditions, synoptic events, and the planetary boundary layer by using atmospheric transport models, climate observations and atmospheric tracers. More specifically, we attempted to answer the following specific questions: how significant is the variability of OCS mixing ratios in an urban ecosystem? What is the land-use influence on the urban OCS budget?

1. Methods

2.1. Study site

The two experimental campaigns took place in the Metropolitan Area of Barcelona (AMB), located in the NE corner of Spain, as shown in Fig. 1. The AMB, with a total surface area of approximately 640 km^2 and over 3.3 million inhabitants (16,160 people/km^2), is the 7th largest urban area and 8th most densely populated region in the European Union. It is also one of the most industrialized areas in the western EU (Querol et al., 2004), specializing in food production, chemicals, vehicle manufacturing, and gas production and distribution (Institut d'Estadística de Catalunya, 2023). The AMB is bounded by the Besós River in the northeast, the Llobregat River in the west, the Collserola mountain range to the north, and the Mediterranean Sea to the south, as shown in Fig. 1. The AMB has a Mediterranean dry

subhumid climate with an annual precipitation of approximately 600 mm, which is mainly concentrated during spring and autumn, and a mean annual temperature of 16.5 °C. The orography of the city extends from sea level to 516 m above sea level (a.s.l.) at the mountain range located northwest of the main urban areas.

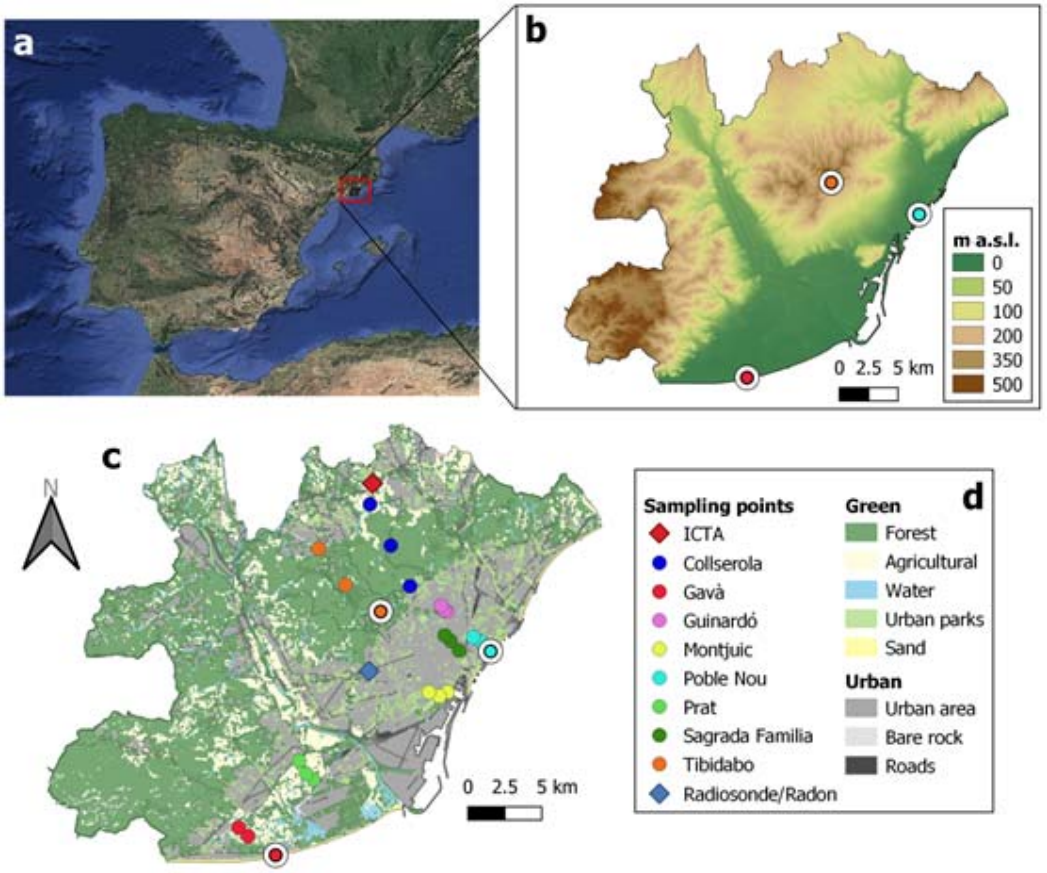

Fig. 1. (a) A map of Spain showing the Metropolitan Area of Barcelona (AMB, red rectangle). Orography of the AMB (b) and land use (c), where triplicates of colored dots represent the upwind, target, and downwind sampling locations (d). Background atmospheric OCS levels were investigated at the upwind sampling points at the sites of Tibidabo (highest altitude in the PBL), Gavà and Poble Nou (closest to the shore). These sites are depicted with colored dots with white circles in b and c. The red diamond represents the location of ICTA and the blue one where the radiosondes were launched and the radon measurements were performed (c).

More than half of the AMB's surface area is covered by vegetation in various forms, including urban forest (43%), agricultural fields (8%) and urban parks (4%), while 41% is covered by

impervious and other infrastructures (4%). Land uses are shaped by the following physical constraints: crops are located in the coastal plains formed by the delta of the Llobregat River, while urban forests composed of pine and holm oaks are located in the Collserola mountain range (Fig. 1). Urban green spaces are scattered throughout the metropolis and populated with ornamental species ranging from acacias to plantain trees and ornamental shrubs and grasses.

2.2. Field campaigns

Air samples were taken at the eight sites shown with colored dots in Fig. 1c, which were selected to represent the heterogeneity of land use throughout the AMB and are summarized into four land-use categories (see table 1): agricultural area (located in the Gavà and Prat areas), urban forest (Tibidabo and Collserola), urban green (Montjuic and Guinardó) and urban (Sagrada Familia and Poble Nou). We took air samples at each site (hereafter referred to as the target site) and upwind and downwind of each target site in an attempt to follow the air mass flow during its trajectory over the target site. The upwind and downwind sampling sites were determined based on historical wind patterns and trajectories typical of each target location under similar atmospheric conditions expected during the campaign and are available from the Meteorological Service of Catalonia (www.meteo.cat) and shown in Appendix S1 of the supporting information. Note that in May and October 2020, observed wind patterns sometimes differed from historical data. The locations of the upwind, target, and downwind sites are shown for each point using the same color in Fig. 1c. The spatial distance among the three sampling points of each site ranges from 500 to 4,000 meters. Sampling times were chosen to capture inland winds during the early morning (i.e., 4:00 and 7:00 UTC am) and the typical sea breezes that develop during the morning and early afternoon (i.e., 9:30 and 11:00 UTC am).

The first campaign took place between May 18th and May 28th, 2020, which was during a period of intense transport restrictions due to the COVID-19 pandemic, and resulted in highly significant air pollution reductions (Badia et al., 2021). Anthropogenic emissions drastically decreased, especially for the aviation (95%), road transport (up to 85%), and more moderately according to shipping (21%), public power %) and industry (11%) sectors (Guevara et al., 2021). The second campaign took place from the 13th to the 27th of October 2020, when the anthropogenic activity returned to normal.

The temperature ranged from 20 °C to 24 °C during May and 14 °C to 20 °C during October. Samples were collected at 7:00 UTC and 9:30 UTC, and for some specific days, we performed additional sampling at 4:00 UTC and 11:00 UTC for the Tibidabo, Gavà and Poble Nou upwind locations to determine the background concentration of OCS. The weather was stable during both campaigns with one day of slight precipitation during each sampling campaign, which accumulated 2.6 and 1.6 mm during May 29 and October 26, respectively. The air mass influence was mostly cyclonic and advective with some days characterized by anticyclonic circulation. Synoptic winds were mostly north and east during the May campaign and predominantly southwest during October as summarized in Table S2 of the supporting information.

We recorded temperature, air pressure, wind direction and wind speed at each sampling site using a portable anemometer (Skywatch Xplorer 4). The relative humidity was obtained from the Meteorological Service of Catalonia for the first campaign (Servei Meteorològic de Catalunya, 2023), and additionally, it was registered on site using a digital hygrometer (TFA Dostmann®, precision ±4%) during the October campaign.

1.3. OCS measurements and analysis

193 Samples were collected in cylindrical borosilicate glass flasks (1 L volume, Normag Labor und
194 Prozesstechnik GmbH, Germany) with Kel-F PCTFE valves fitted at both ends. This flask
195 material showed the lowest permeation of gases compared to other sealing materials (Sturm
196 et al., 2004). To ensure the quality of the measurement technique and repeatability of the
197 experiment, two flasks connected to each other in a portable device were simultaneously filled
198 in series (see Appendix S2, Urban sites, for device pictures). The inlet was installed at 3.5 m
199 above ground level (m a.g.l.) and air, after passing through a magnesium perchlorate desiccant
200 tube to remove moisture and a filter to remove particles, was pumped to the flasks with the
201 help of a diaphragm pump (KNF N84.4 ANDC). Before taking the sample, air was flushed
202 through the flasks for at least 10 min. At that time, we checked that the flow was steady and
203 between 2.0 L min^{-1} and 3.5 L min^{-1}. After flushing, the exit valve was closed, and the flasks
204 were pressurized with sample air to approximately 1.5 bar. Samples from the target, upwind
205 and downwind sites were taken at the exact same moment to simulate an Eulerian
206 approximation in which the sampling point remains fixed (Leelőssy et al., 2016).

207 Flasks were sent to the Laboratoire des Sciences du Climat et de l'Environnement, LSCE, Paris-
208 Saclay, France, for OCS analyses. Flasks were stored for a maximum of 2 months before
209 analysis. OCS was analyzed following the analytical method described in Belviso et al. (2016)
210 and Belviso et al. (2022). In this procedure, atmospheric OCS (500 ml) is trapped using an
211 automated sampling system (Entech P7100 preconcentrator) and then analyzed by gas
212 chromatography with pulsed flame photometry detection (PFPD, Varian Model 3800, Belviso
213 et al., 2016). Calibration was performed every week using a calibration gas supplied by Air
214 Products (Belviso et al., 2016). The difference between the assigned value of an NOAA long-
215 term air standard (NOAA-2004 scale) and the average of multiple analyses of that same
216 standard was smaller than 1.5%. The drift between calibrations was assessed on a daily basis
217 using a short-term target gas (Belviso et al., 2016).

1.4. Determining the planetary boundary layer height

It is necessary to determine the planetary boundary layer height (PBLH) to understand its influence on the accumulation and dilution of OCS concentration at each site over the urban area. PBLH measurements were not possible at the eight target sites, but at least the PBLH was calculated from measurements taken on the campus of the University of Barcelona (Fig. 1, label: Radiosonde/Radon) using two different techniques as follows: (1) based on observed measurements from a radiosonde (RSD) station installed on the roof of the Physics Department of the University of Barcelona (41°23'03'' N 2°07'01''E), which is part of the Global Meteorological Network (GCOS, 2016); and (2) via a laser ceilometer (CL-31, Vaisala Inc., Finland) located at the same place with a measurement range up to 7.6 km, 10-m vertical resolution and a temporal resolution of 16 s. For the latter, the PBLH is estimated from the ceilometer data using the Vaisala Boundary-Layer View software (BL-VIEW) Enhanced Gradient method (VAISALA, 2020) – see details in Garcia-Dalmau et al. (2021) - followed by selection algorithms according to the methodology of Lotteraner et al. (2016).

To determine the PBLH based on radiosonde measurements, we followed a robust numerical procedure proposed by Liu and Liang (2010) using midday radiosonde (RSD) observations from the selected periods of study and considering 1100 UTC as the launching time. The PBLH was computed following the air parcel method for a convective dominated boundary layer (Holzworth, 1964; Seibert et al., 2000; Stull, 1988) as the height where air parcel evolution following a dry adiabatic evolution from surface intersects with the environment temperature profile. The calculated PBLH from RSD was visually corrected to solve the method errors and mostly related to the presence of several temperature inversion layers. A detailed explanation of the method and how we applied it to our case study is presented in the supplementary material (Appendix S3).

In this study, we also analyzed radon, which is a radioactive and noble gas known to be a good atmospheric tracer (Grossi et al., 2012), to better understand the evolution of the PBLH and to corroborate the PBLH calculated from the ceilometer observations using the method proposed by Griffits et al. (2013). Hourly atmospheric concentrations of Rn were measured during October 2020 using an Atmospheric Radon MONitor (ARMON) at the Barcelona School of Industrial Engineering station (41°23'03'' N 2°07'01''E, 10 m a.g.l) at the same site that radiosonde and ceilometer data were recorded and identified with the label Radiosonde/Radon in Fig. 1c. The monitoring was designed and built by the Universitat Politècnica de Catalunya as described by Grossi et al. (2012). Due to COVID-19 restrictions, no radon data were recorded for May 2020 because the equipment had to be shut down.

The estimations of PBLH using radiosonde and ceilometer were also compared with PBLH simulated using the Weather Research and Forecasting model (WRF). WRF simulations were performed to obtain information on the main transport processes and the vertical mixing conditions throughout the AMB as described in Section 2.6.

1.5. WRF simulations of the urban atmosphere

The WRF v4.3 model (Skamarock et al., 2021) coupled with the multilayer urban canopy scheme BEP-BEM (Salamanca et al., 2010) was used in this study to simulate the urban atmosphere over the AMB to better understand the influence of local weather conditions and PBL development on OCS concentrations. The WRF configuration used for this study consists of 3 two-way nested domains with horizontal resolutions of 9 km, 3 km, and 1 km covering the Iberian Peninsula, the Catalan territory, and the AMB, respectively, with 45 vertical layers up to 100 hPa (see Fig. S2 in Supporting information). The physics parameterization for the planetary boundary layer is the Boulac scheme, which has been shown to be the most suitable to resolve the turbulence intensity in convective situations for the AMB (Segura et al., 2021). We included 11 urban local climate zone (LCZ) classifications (Stewart and Oke, 2012) for the

innermost domain and each had a specific value for thermal, radiative and geometric parameters of the buildings and ground, which are used by the BEP-BEM to compute the heat and momentum fluxes in urban areas (Gilabert et al., 2021; Ribeiro et al., 2021; Yu and Steinberger, 2011). We conducted simulations for May and October 2020 using meteorological initial and boundary conditions from ERA5 (Copernicus, 2023). Table S3 in the supporting information further describes the model characteristics and experimental configurations. The model simulations were validated using temperature, wind speed and wind direction observations from 14 meteorological stations of the Meteocat network (https://www.meteo.cat/observacions/xema).

1.6. FLEXPART back trajectories

FLEXPART back trajectories were calculated to determine the precedence of air sampled at the various sites to establish whether the air mass influence was local or regional. FLEXPART (FLEXible PARTicle dispersion model) is a Lagrangian transport and dispersion model that is used for calculating the long-range and mesoscale dispersion of air pollutants (Stohl et al., 2005). The FLEXPART version adapted to the WRF mesoscale model (Brioude et al., 2013) was used to calculate back trajectories of air tracers from each of the sampling sites at the sampling times. The back trajectories were computed from the output of the WRF model at the nested domain of 1 km with 16 vertical levels from 0 to 2000 m a.g.l. Each back trajectory was calculated for 24 h after the sampling time. The number of particles released to the atmosphere in the simulation was 2000. From the 3D back trajectories, only the layers from 0 to 100 meters above ground level were used for the study of footprints, as it is where the exchange among the land/ocean - atmosphere takes place.

2. Results

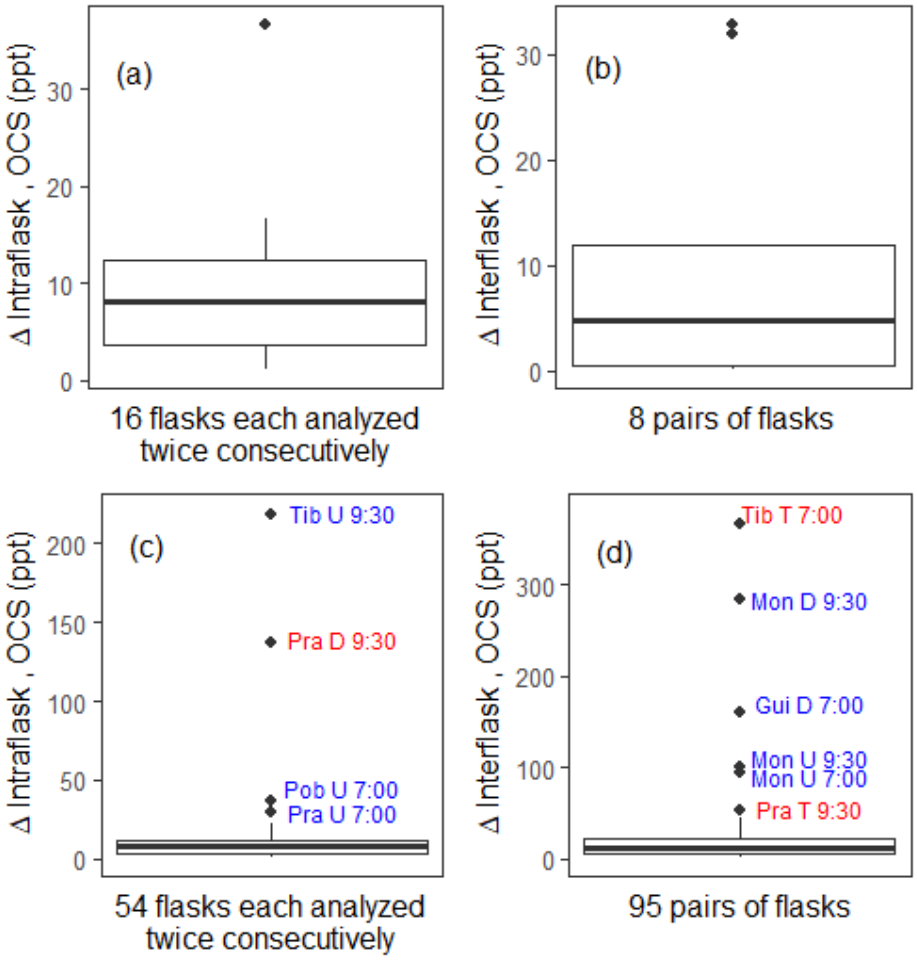
3.1. OCS sample repeatability and accuracy in urban environments

We performed a precision analysis of the GC measurements of flask-air samples according to the methods developed by Belviso et al. (2022) to assess the repeatability and accuracy of the OCS measurements in an urban environment. Eight pairs of flasks in total were selected randomly from the May and October campaigns, and each flask was analyzed twice consecutively for OCS. The average difference between duplicated measurements, i.e., the intraflask difference, was 9.8 ± 8.7 ppt (median = 8.2 ppt, interquartile range (IQR) = 3.6–12.7 ppt, n = 16, 90^{th} percentile = 16.5 ppt, 6.3% of outliers), as shown in Fig. 2a. It was slightly higher than that reported by Belviso for samples collected in a rural area over wheat and rapeseed crops (Belviso et al. (2022), i.e., 9.3 ± 7.2 ppt (median = 7.5 ppt, interquartile range (IQR) = 4.5–12.5 ppt, n = 58, 5.2% of outliers, but in that case, the 90^{th} percentile was 19.5 ppt). Fig. 2c shows that among the 54 flasks (each analyzed twice consecutively), four displayed mixing ratios higher than the 90^{th} percentile (i.e., 22.9 ppt), while the median and IQR of the intraflask difference (7.7 ppt and 3.3-12.1 ppt, respectively) appear to be highly consistent with the data displayed in Fig. 2a. Consistency is also found in terms of the proportion of aberrant determinations of OCS mixing ratios (i.e., 6.3% (Fig. 2a) and 7.4% (Fig. 2c)). It was concluded that the precision for GC measurements of flask-air samples remained unchanged over the two campaigns and was consistent with that reported by Belviso et al. (2022).

The average difference between flasks of the same pair (i.e., the interflask difference) was also analyzed in a duplicate manner and was 10.1 ± 14.0 ppt (median = 4.8 ppt, IQR = 0.05–18.6 ppt, n = 8, no outlier, Fig. 2b). Hence, the interflask difference during the AMB study displayed higher variability than that of Belviso et al. (2022), i.e., 5.5 ± 4.5 ppt (median = 4.9 ppt, IQR = 2.2–8.0 ppt, n = 29, a 6.9% proportion of outliers was reported in that study). The interflask difference was also assessed from a single analysis of the content of each flask. The median, IQR and 90^{th} percentile were 12.1 ppt, 4.3-22.5 ppt and 45.0 ppt, respectively, with n= 95 (Fig. 2d). We reported the existence of six outliers (i.e., a proportion of 6.3%) exhibiting interflask

differences higher than 45.0 ppt and up to 360 ppt. The interflask difference calculated from pairs of flasks each analyzed only once for OCS (Fig. 2d) displays higher variability than that from pairs of flasks analyzed twice consecutively (Fig. 2b).

Consequently, although the four outliers displayed in Fig. 2c should have been discarded, we arbitrarily reincorporated those exhibiting intraflask differences in the range of 22.9 ppt (i.e., the 90^{th} percentile) and 36.8 ppt. According to Belviso et al. (2022), data from pairs of flasks exhibiting interflask differences higher than 14 ppt should be discarded. Note that this threshold is approximately twice that set by Montzka et al. (2007). Although the interflask difference calculated from pairs of flasks each analyzed only once for OCS could originate from aberrant data (Fig. 2d), nobody ever documented the high frequency distribution of OCS mixing ratios next to potential urban sources of that gas. In other words, although flasks are supposed to be simultaneously filled in pairs, the process of pressurization of two flasks connected in series could generate concentration gradients reflecting the heterogeneous distribution of OCS next to potential urban sources of that gas. In light of this possibility, we decided to arbitrarily validate the six outliers reported in Fig. 2d and investigate whether interflask differences higher than 45 ppt would be site dependent or would result from aberrant data.



334

335 **Fig. 2.** Analysis precision for OCS measurements from flask-air samples collected in the AMB
336 showing the 10th, 25th, median, 75th and 90th percentiles. (a, c) show Δ interflask differences
337 in OCS concentration between two consecutive analyses of the content of each flask (median
338 of flask 1 minus that of flask 2), whereas (b, d) show the Δ interflask differences in OCS
339 concentration between flasks of the same pair. The diamonds correspond to the outliers (>
340 90th percentile), which are over 23 ppt in Fig. 2c and over 45 ppt in Fig. 2d. Outliers are labeled
341 according to the location and time of sample collection. The codes of each sampling site are
342 site, location and time UTC (sites: Tib: Tibidabo, Pra: Prat, Pob: Poble Nou, Mon: Montjuic, Gui:
343 Guinardó; location: U: Upwind, D: Donwind, T: Target). Note that historical wind data was used
344 for that purpose. The label colors represent the campaigns and correspond to red for May and
345 blue for October.

3.2. Evaluation of WRF simulations

We ran WRF BEP-BEM simulations in May 2020 and October 2020 to obtain high-resolution meteorological data, atmospheric stability, and PBLH during the sampling periods. Statistical analyses of the root-mean-square error (RMSE), mean bias (MB) and correlation factor (R) were used to evaluate performances of the model compared with ground-based meteorological observations from Meteocat (see Section 2.6). The near-surface relative humidity (RH), temperature (T) and wind speed (WS) statistical analyses are displayed in Figs. S3 and S4 for campaigns in May and October, respectively. There is an overall good performance for the modeled RH, T and WS in comparison with the observations with an average error of ±14% for RH, ±1.7 to 1.9 °C for T and ±1.65 ms-1 for WS. This statistical analysis is available in the supporting information in Table S4.

During the May campaign, there were predominant northerly winds from the north from the 18th until the 21st, and the circulation weather types were hybrid-cyclonic to cyclonic regimes, while the second half (25th through the 28th) was characterized by winds from the east with a Mediterranean Sea air mass influence and adventive regimes, with the exception of the 28th, which was anticyclonic with a southeast synoptic wind component and local maritime air mass influence. During the October campaign, westerly and southerly winds characterized by adventive circulation weather types prevailed for most of the period with a cyclonic north influence and regional continental air mass in the first two days switching to a maritime influence for the rest of the campaign. Table 1 summarizes these weather patterns for each day of the two campaigns.

Table 1. Circulation weather type (CWT), synoptic wind component (SWC) and PBLH extracted from WRF simulations expressed in meters above ground level (a.g.l), averaged OCS concentrations of all measurements taken each day during the May and October campaigns, and expressed in ppt (mean values from the 3 sites, mean values ± standard deviations). An unabridged version of this table with upwind and downwind OCS including a detailed data for background measurements concentrations (see figure 4) is available in S1 of the supporting information.

Campaign	Site (elevation)	Land use type	Date	CWTs*	SWC**	PBLH range (m)	OCS 7:00 UTC (ppt)	OCS 9:30 UTC (ppt)
May 2020	Tibidabo (175-442 m)	Forest	19/05	C	N	19-441	478±20	494±9
	Gavà (0-2 m)	Agricultural	21/05	U	N	11-249	482.1±NA	495.5±10.7
	Poble Nou (0-4 m)	Urban	21/05	U	N	44-2217	461±20	NA
	Montjuic (42-98 m)	Urban green	20/05	C	N	327-883	485±14	490±5
	Prat (0-2 m)	Agricultural	25/05	E	E	737-1182	502±NA	508±2
	Sagrada (37-55 m)	Urban	26/05	E	E	771-1900	460±6	NA

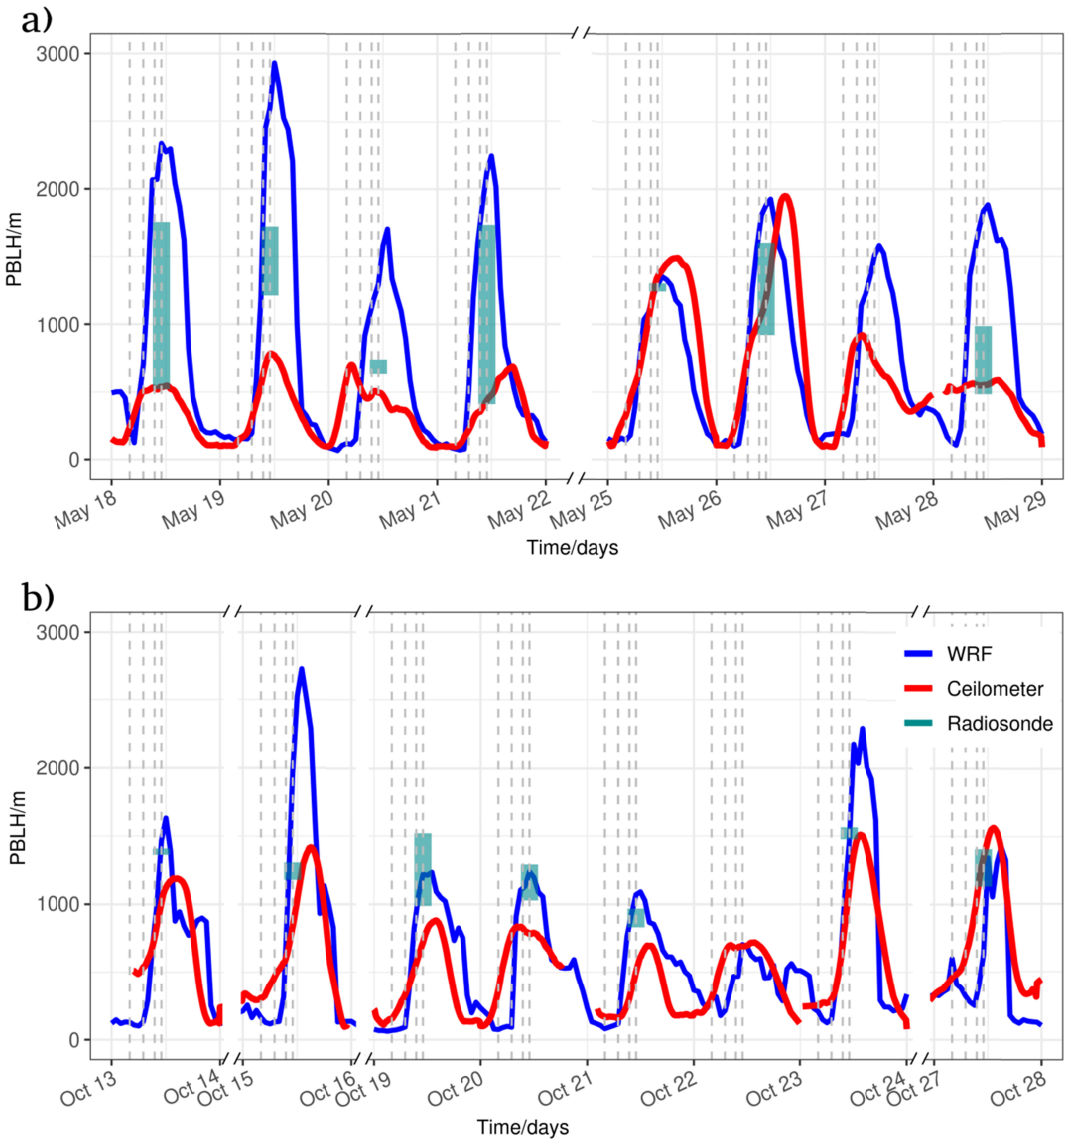
***CWT:** Circulation weather type. The different types of CWTs are cyclonic (C), anticyclonic (A), pure advective (N, S, E, W, NE, SE, NW, SW), hybrid cyclone-advective (CN, CNE, CE, CSE, CS, CSW, CW, CNW), hybrid anticyclone-advective (AN, ANE, AE, ASE, AS, ASW, AW, ANW), and undefined (U). ****SWC:** Synoptic wind component summarizing the pressure pattern, fronts, wind direction and speed.

3.3 Planetary boundary layer height calculations and evaluation

The PBLH from the WRF BEP-BEM simulations was compared against ceilometer estimations and radiosonde observations at 11:00 UTC for each day of the campaigns (see Fig. 3). All data

383 time series follow the expected PBLH diurnal pattern with a rapid growth of the PBLH during
384 the morning, a maximum that was reached at midday, and a decrease during the afternoon.
385 The PBLH calculated by the WRF model is generally higher than that estimated by the
386 ceilometer and radiosonde. During the first period of May and first days of October when
387 there are continental regional air masses with prevailing large-scale northern winds, we
388 noticed an important difference between the ceilometer, radiosonde, and WRF values in some
389 cases up to 150 m difference at 11 UTC. In this situation, the large-scale winds dominate the
390 boundary-layer scales, which limit the capacity of the WRF model to estimate the PBLH and
391 leads to high uncertainty in the radiosonde observations (Stull, 1988).The inverse correlation
392 between atmospheric radon concentrations and the ceilometer-based PBLH is uniformly
393 maintained during the entire October campaign as you can see in Fig. S5 how PBLH are at is
394 maximum at 00:00 UTC while atmospheric radon concentration are at its lowest, and the
395 opposite behavior is seen around 12:UTC (see Fig. S5and Fig. S6 of the supporting
396 information), which further indicates an overestimation of the PBLH by WRF during strong
397 wind events in early October. The highest radon activity concentrations (between 0.01 Bq m^{-3}
398 and 0.05 Bq m^{-3}) are observed during nighttime (21 h-2 h) when the PBLH reaches its
399 minimum, whereas the lowest values (between 1 Bq m^{-3} and 2 Bqm^{-3}) are observed during
400 diurnal hours (11 h-16 h) when ^{222}Rn is diluted due to a well-developed PBL.

401 The overestimated PBLH modeled values in May are consistent with an overprediction of the 2
402 m temperature seen for a station located 1.2 km from the radiosonde launching location. In
403 contrast, better agreement between the modeled and observed PBLH (both radiosonde and
404 ceilometer) is seen during the second half of the May campaign from the 25^{th} to 28^{th} of May
405 (Fig. 3a), when the easterly winds lead to a more stable atmosphere. October showed better
406 agreement overall among the PBLH values obtained from the ceilometer, RSD and WRF model
407 due to higher atmospheric stability. The south-easterly weak winds generally lead to stable
408 conditions and local scale dominance where the PBLH can be well estimated.



410

414 **Fig. 3** The time series of modeled PBLH (blue line) together with the Ceilometer (red line) and
415 the Radiosonde (blue shade) for a) May and b) October campaigns. Shaded blue areas indicate
416 the PBLH using two different definitions for its calculation. Vertical lines correspond to the 4
417 am, 7 am, 9:30 am and 11 am UTC sampling times on a daily basis.

415 **3.4 WRF-FLEXPART footprints**

418 FLEXPART simulations showed that the sampling campaign covered different synoptic
419 situations and different air mass origins. Appendix S4 of the supporting information shows that
420 during the May campaign, two main directions were observed as follows: one coming from the

418 northwest following the Llobregat River basin (days 18, 19, and 21 of May) and another from
419 the northeast with more sea influence (days 20 and 25 of May) and some others with more
420 land influence (such as days 26, 27, and 28 of May). Generally, the simulation at 09:30 UTC
421 shows more sea origin of the air masses arriving at sampling points than the simulations at
422 07:00 UTC in accordance with the sea–land breeze regimes.

423 During the October campaign, the air masses mainly came from the northwest following the
424 Llobregat River basin (days 15, 19, and 27 of October), although a situation with strong winds
425 coming from the south was observed between the 20th and 21st of October. A stronger breeze
426 regime is observed during this month with general changes in the origin of air masses between
427 the simulations at 07:00 and 09:30 UTC.

428 **3.5. Background OCS measurement validation**

429 There were three potential background measurement locations (upwind sites of Gavà, Poble
430 Nou and Tibidabo shown in Fig. 1), but only Tibidabo at 442 m a.sl showed stability in OCS
431 concentrations regardless of the diurnal convection patterns (Fig. 4a), which ranged from 443
432 to 507 ppt during May and 392 to 416 ppt during October, as shown in Fig. 4b. The coastal
433 sites showed less stable values with Gavà showing the highest variability ranging from 407 to
434 600 ppt during May and 393 to 489 ppt in October, which are values well above the global
435 background level. For example, on May 18th, a great variability in OCS mixing ratios was
436 observed, and FLEXPART back trajectories simulated for Gavà showed significant changes in air
437 mass precedence (see Appendix S4a: Gavà, May 18, 2020, at 7:00, 9:00, and 11:00 UTC). At
438 7:00 UTC, we obtained the lowest OCS concentration value of the campaign (407 ppt) when air
439 masses came from the inland north and collected air from forested areas; a few hours later at
440 9:30 UTC, the concentration rose to 600 ppt because air transport switched to an influence
441 from the northeast where the densest part of the AMB is located. Earlier and later that day, at
442 4:00 and 11:00 UTC, OCS measurements were closer to typical background values, which

indicated the marine influence of sea breezes during those hours, which decreased residential times over the urban area. Thus, we established Tibidabo mean values as a background measurement with a mean value for OCS of 484 ppt in May and 407 ppt during October. Our Tibidabo background values show congruence with those of the National Oceanic and Atmospheric Administration (NOAA), which ranged from 478 to 498 ppt in May and 399 to 408 ppt in October (https://gml.noaa.gov/hats/gases/OCS.html).

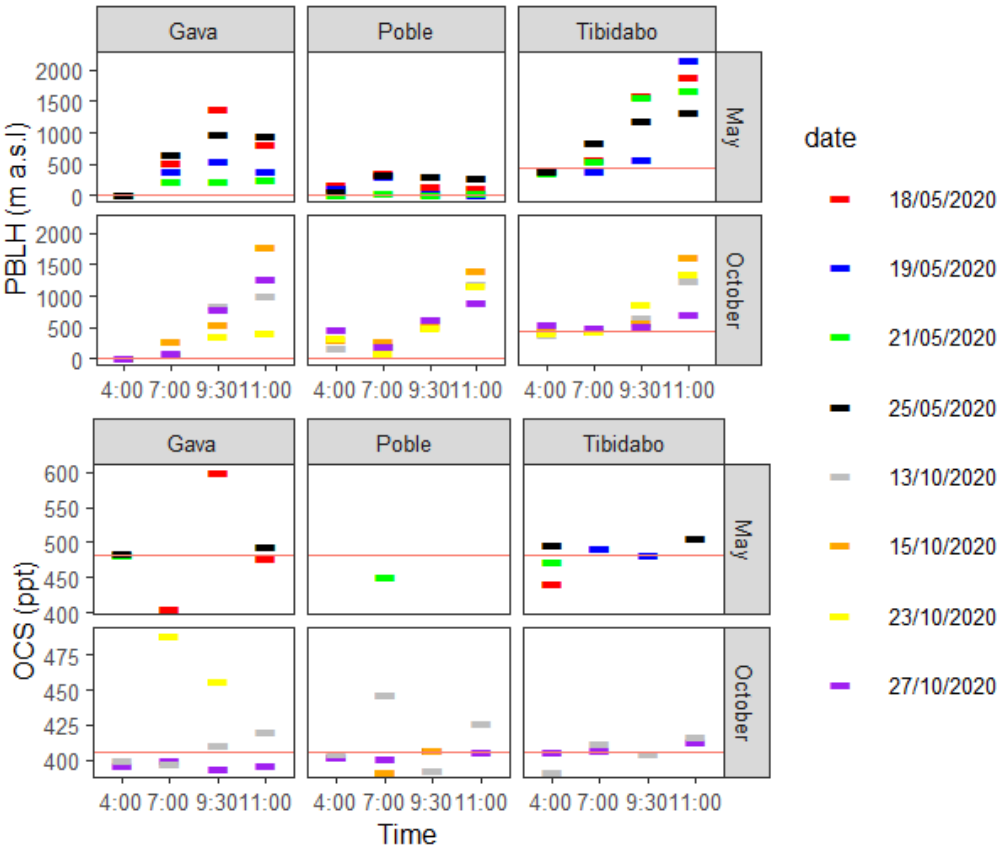


Fig. 4. (a) PBLH from the WRF model of three potential background site measurements for the AMB. The red line represents the current altitude for each site. (b) OCS concentrations of three potential background measurements for the AMB. The red line represents the background value chosen, which corresponds to the Tibidabo site with mixing ratios of 484 and 407 ppt for the May and October campaigns, respectively. Detailed data for background measurements concentrations is available in S1 of the supporting information.

458 Generally, OCS background concentrations were higher in May (484 ppt) than in October (407
459 ppt), which reflects the global annual oscillation of maximum values in spring (mean north
460 hemisphere 510 ppt for May) and lowest values in the fall (mean north hemisphere 440 ppt for
461 October) reported by Montzka et al. (2007) for northern hemisphere Atlantic locations.

462 **3.6. OCS concentrations over the metropolitan landscape**

463 The OCS concentrations at each site for both campaigns are given in Table 1, which also
464 provides the circulation weather type (CWT), the synoptic wind component (SW) and PBLH
465 from the WRF model simulations. The full data set is available at the Zenodo repository
466 (URBAG, 2023) as well as the supporting information table S1. The highest concentrations
467 were recorded in May at the sampling sites of Guinardó and El Prat (612±17 ppt and 508±2
468 ppt) when winds were coming from the east, independently if mass air influence was local or
469 regional, and well above ocean background values of 478 to 498 ppt estimated at the North
470 Atlantic locations by NOAA (Fig. S7, https://gml.noaa.gov/hats/gases/OCS.html). High-
471 pressure, anticyclonic conditions during that time suggest that the high OCS concentration
472 values might be due to the accumulation of local OCS emissions.

473 The lowest OCS concentrations were recorded at Gavà and Collserola in May (407.1±8.5 and
474 412.6±13.8 ppt, respectively) and at Gavà, Guinardó, Sagrada Familia and Poble Nou in
475 October (398.3±6.1, 374.1±8.6, 397.3±5.2, and 390.4±15.7, respectively). There seems to be no
476 clear pattern relating circulation weather typologies to OCS measurements. For example, the
477 highest OCS mixing ratio during the October campaign was recorded in Montjuic at 7:00 UTC
478 (485±87 ppt) with hybrid cyclone-advective conditions that influenced the day and regional air
479 mass with wind blowing from the southwest (Table 1). In October, we had a similar weather
480 pattern, yet this location registered one of the lowest OCS concentrations (389±20 ppt).
481 However, Sagrada Familia also recorded the second lowest value (392±16 ppt) in October with

maritime stable conditions on both days. For May, the lower record corresponds to Gavà at 7:00 UTC (431±22 ppt), which was a day with local continental atmospheric conditions.

4. Discussion

4.1. Exploring the land-use influence on the OCS budget of the urban area.

We found more variability among the OCS mixing ratios within the metropolitan area than between the two campaigns, which ranged from 450 to 600 ppt for May and from 390 to 470 ppt for October. This indicates that local sources and sinks, the heterogeneity of the urban landscape, and local air transport in the AMB have a larger weight on the OCS urban budget than what other stations that monitor more homogenous areas, such as Gif-Sur-Yvette and Mace head, than within cities such as Utrecht (Fig. S7). We proceeded to analyze how each type of land use had an influence on OCS concentrations, considering other measured or modeled variables such as air transport regimes, PBLH development, and air mass influence.

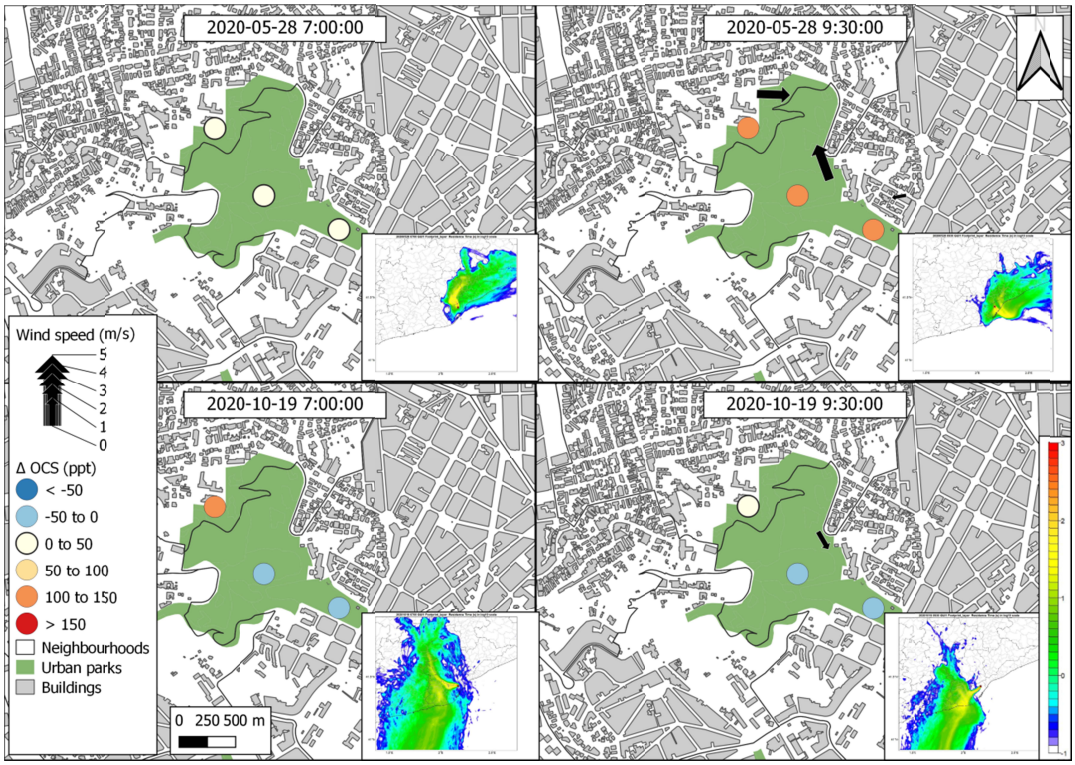
Urban parks: Samples were measured from two urban parks located in very different urban environments in the AMB (see Fig. 1 for their locations and supporting information and Appendix S2 for pictures). Guinardó Park is located in the middle of Barcelona in one of the most densely populated areas, which is characterized by a high built fraction and surrounded by streets with heavy traffic. At 169 m a.s.l and a total area of 15.9 ha, Guinardó has dedicated spaces for recreational purposes and a wide number of ornamental trees including acacias, magnolias and other foreign species. However, Montjuic Park is close to the sea and overlooks the Port of Barcelona at 98 m a.s.l. with a total area of 227 ha. It is part of a highly vegetated recreational area on Montjuic Mountain with more than 690 species of identified plants including palm trees, acacias, pines, and a great variety of shrubby plants.

Guinardó was sampled on May 28TH at 7:00 and 9:30 UTC with little presence of local winds at that time. Fig. 5a shows the OCS enhancements (Δ OCS) calculated as the measured OCS

concentration at each site minus the background concentration of 484 ppt established for the month of May (Table S1 in supporting information can be consulted for absolute values). Initially, at 7:00 UTC, OCS concentrations at downwind, target, and upwind, were +22, +28, and +11 ppt, respectively over the established background level of 484 for May showing little enhancement; however, at 9:30 UTC, we observed a significant ΔOCS of +110, +128, +144 ppt, respectively. FLEXPART backward trajectories for these times (embedded in Fig. 5a and b, while a larger Fig. is provided in Appendix S4) estimate that the forthcoming air masses were mostly local with breezes changing from land (north–east) at 7:00 to sea (southeast) at 09:30 UTC. This suggests local sources of OCS from both the sea and industrial activity of the port. Overall, it seems that the OCS capture capacity by the vegetation of Guinardó Park is offset by significant local sources that are perceptible when wind blows from SE (Locations abected by port, city and ship traffic), which increase OCS concentrations by +140 ppt despite a highly developed PBLH of 1,524 m at 9:30 UTC, which favors mixing and lower concentrations.

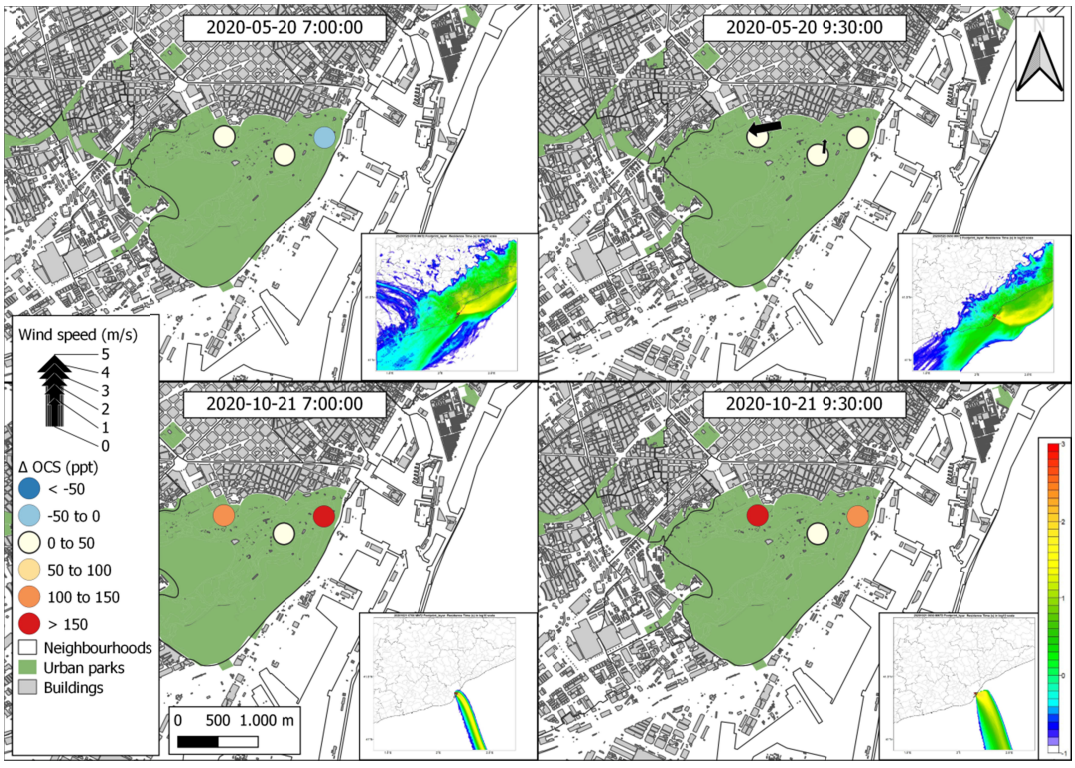
Samples taken on October 19th showed the opposite behavior as follows: ΔOCS were -33, -4, and +113 ppt for the downwind, target, and upwind directions, respectively, at 7:00 and -15, -32, +2, ppt, respectively, at 9:30 UTC, as shown in the lower panel of Fig. 5a. This time, the FLEXPART backward trajectory indicates a regional air transport influence from the northwest at 7:00 UTC, which transports air masses from the agricultural Llobregat basin. At 9:30 UTC, winds switch to southwest collecting air with influences from croplands and the sea. Furthermore, local breezes were insignificant, and the PBLH did not develop very strongly between 7:00 and 9:30 am, going from 69 to 934 meters, which leads us to believe that the lower concentrations at both 7:00 and 9:30 are most likely attributable to vegetation uptake in the park and the influence of air mass transport from agricultural fields rather than mixing of air that is typical of a fully developed boundary layer.

532 a) Guinardó



533

533 b) Montjuic



534

Fig. 5. OCS enhancement (Δ OCS) in ppt calculated as measured OCS minus background OCS (484 ppt for May and 407 ppt for October) for each campaign at the two urban parks as follows: a) Guinardó and b) Montjuic. The black arrow shows the wind direction and speed measured on site, and the absence of an arrow indicates that there was no wind blowing at the moment of measurement. A small map embedded in the lower right-hand corner of each panel shows the residence time on a logarithmic scale of the air masses arriving at the sampling site as determined with the FLEXPART model.

Montjuic Park offers more information in terms of the OCS drawdown capacity of the vegetation because of its key location next to the Port of Barcelona, which is expected to be a source of OCS due to its natural gas supply activity and ships. As illustrated in Fig. 5b, there was very little difference between the 7:00 and 9:30 UTC OCS enhancements during May, which ranged from -12 to +17 ppt. The FLEXPART simulation for that day indicates a regional sea influence from eastern winds at 7:00 and 9:30 UTC that explains why all sites have OCS concentrations very close to background values at both times. There seems to be no significant source of OCS over the Montjuic area since the easterly winds are not influenced by the Port of Barcelona, which lies further south.

In contrast, during the October campaign, there was a strong southern regional influence on air masses over Montjuic Park as described by the FLEXPART trajectory. The air arrived from due south with no land influence, which, in addition to a low PBLH at 9:30 UTC of 561 meters, constrains any changes in the OCS budget over Montjuic Park to very local processes. Thus, the high OCS values of 665 and 635 ppt we see at 7:00 and 9:30 UTC for the upwind site and downwind site and reaching more than +150 ppt above background, are most likely a result of the industrial activity of the Port of Barcelona. This enhancement was consistently seen in all upwind and downwind samples at 7:00 and 9:30. At the target site, samples were consistently near background values with enhancements of only +16 and +18 ppt at 7:00 and 9:30 UTC, respectively. It is more difficult to determine the reasons for this decrease compared to the other two points; it could not receive the emission plume that reached the other two places and combined with an effect of the vegetation signal. The fact that the target is at double the

562 height of the upwind and downwind sites (98 m asl vs. 58 and 42 m asl) leads us to think that
563 the signal from the plume with a high content of OCS did not arrive with the same intensity.
564 The PBLH was 92 m at 7:00 UTC but 720 m at 9:30 UTC, which could only explain this
565 difference in the early hours.

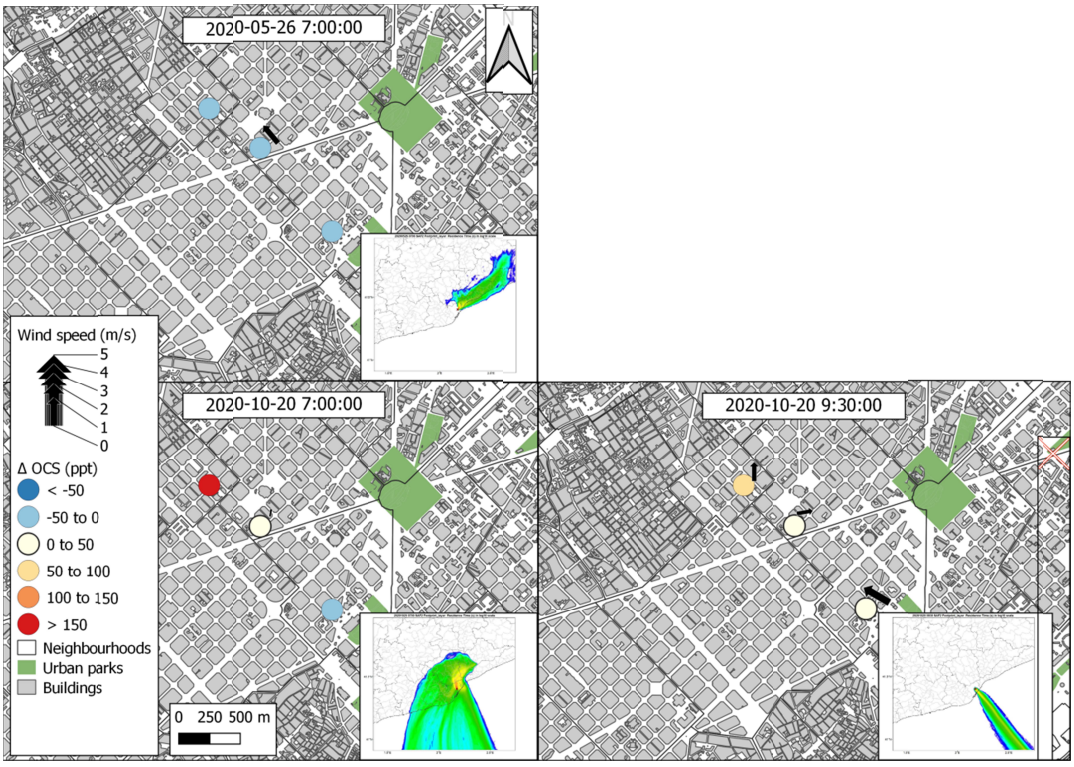
566 **Urban forest.** There were two sampling locations representing urban forests as follows:
567 Tibidabo and Collserola. Both locations belong to the Collserolla range, which is a mountainous
568 area with more than 8,000 ha located in the northern limit of the city with a maximum altitude
569 of 512 m asl. The flora of the park is maritime Mediterranean and is dominated by white pine
570 (*Pinus halepensis*) and low vegetation of maquis, scrub and meadows apart from cultivated
571 fields. It has an estimated population of 10 billion trees and more than 1,000 species of plants.
572 During the May campaign, OCS concentrations at 7:00 UTC ranged between 463 and 499 ppt
573 and 412-498 ppt for Tibidao and Collserola, respectively, which are all within the range of the
574 assigned background concentration. There was one exception at the Tibidabo Target site at
575 7:00, which had 620±260.2 ppt and was discarded as the outlier with the largest discrepancy
576 between replicates (see Fig. 2). Enhancements were minimal with ΔOCS of -16, -72 and -33 ppt
577 for collserola, +7 and -21 ppt for Tibidabo at 7:00 UTC, +9, +14 and +15 ppt for Collserola, and -
578 2, +15 and +15 ppt for Tibidabo at 9:30 UTC. We had local and regional air mass influences and
579 marine to continental winds for Collserola and Tibidabo (see Fig. S8 and Table 1). Local winds
580 at/:00 UTC in Collserola suggested that the small OCS drawdown was due to the vegetation.
581 The forest sites clearly showed a behavior from neutral to sink with respect to OCS exchange
582 fluxes. Having established this tendency, we limited the sampling to the background location
583 (Tibidabo upwind) during the October campaign.

584 **Urban**: OCS concentrations in May were surprisingly lower than our background estimate for
585 both of our urban locations of Sagrada Familia and Poble Nou, which are characterized by
586 100% built environments of buildings, streets, constant traffic and little or no vegetation (see

Fig. 1 for their locations and supporting information and Appendix S2 for pictures). The OCS enhancements ranged between -17 to -29 ppt and 0 to -36 ppt for Sagrada Familia and Poble Nou, respectively, at 7:00 UTC, as shown in the upper panels of Fig. 6 (9:30 UTC samples were not possible because of complications with the logistics during the campaign). Given the low mixing potential of the relatively low PBLH for both the Poble Nou and Sagrada Familia (100 and 800 m, respectively), we can conclude that there were no local OCS sources. One likely reason for this is that there was little or no traffic during this time due to the COVID lockdown and mobility restrictions. The FLEXPART trajectory for Sagrada Familia shows an influence of easterly winds bringing air from the sea. However, we discarded the regional influence on OCS transport because the urban sampling locations were surrounded by buildings. Instead, we assume that local winds have a higher weight on OCS transport, and we were not able to measure any significant local winds.

a) Sagrada Familia

b)



c) B) Poble Nou

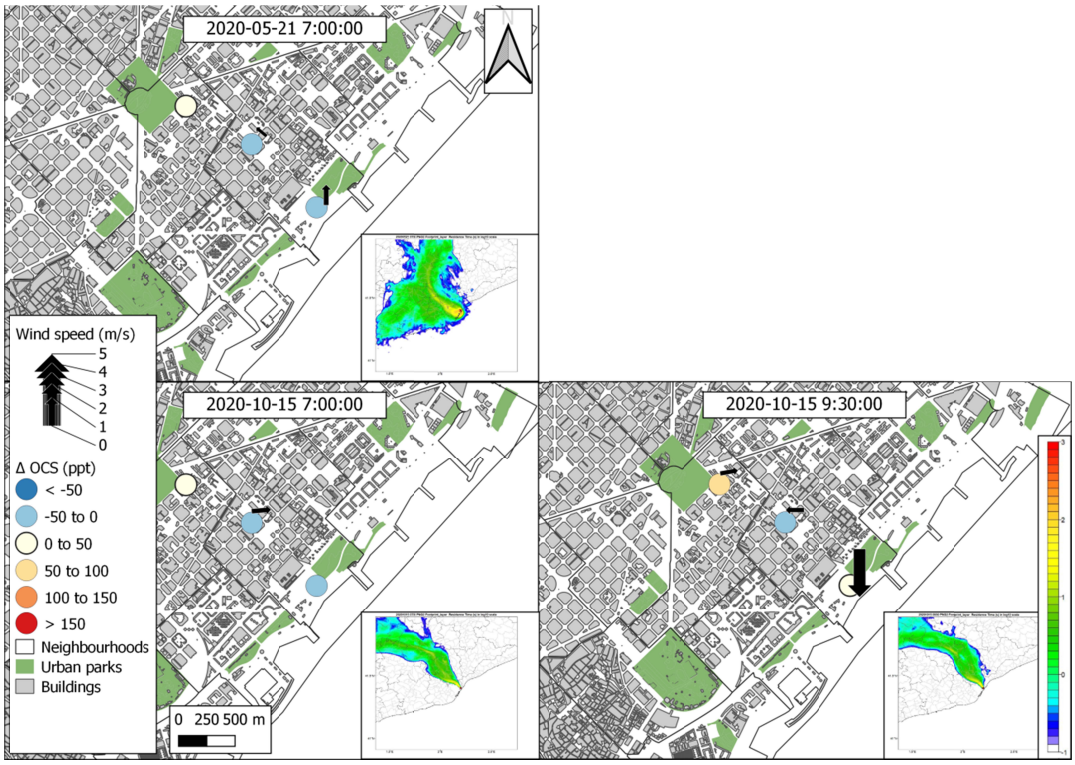


Fig. 6. OCS enhancement (Δ OCS) in ppt and calculated as measured OCS minus background OCS (484 ppt for May and 407 ppt for October) for each campaign at the two urban parks as follows: a) Sagrada Familia and b) Poblenou. The black arrow shows the wind direction and speed measured on site, and the absence of an arrow indicates that there was no wind blowing at the moment of measurement. A small map embedded in the lower right-hand corner of each panel shows the residence time on a logarithmic scale of the air masses arriving at the sampling site and determined with the FLEXPART model.

During the October campaign, there were no more mobility restrictions, and vehicle use was back to business as usual. OCS concentrations were higher than background values in both urban areas, as shown in the lower panels of Fig. 6. In the Sagrada Familia, the downwind location at 7:00 UTC had a record-high ΔOCS of +150 ppt, which was most likely capturing a local source of OCS since the close-by target and upwind sites registered + 7 and -7 ppt, respectively. The FLEXPART model indicates an influence of air mass with long residence coming from the city, which together with a low PBL (approximately 30 m) and the absence of local winds suggests that this peak of OCS is due to a nearby source of emission that was not

present for the other two sampling sites. At 9:30 UTC, the air transport regime changes, and we observe a marine influence. The PBL development increases to 1085 m, and we also observe an increase in local winds (Fig. 6). Even in the midst of this increased air mixture and neutral OCS transport, ΔOCS increases up to 57 ppt, which points to local OCS sources in this urban area.

The other urban site, Poble Nou, did not exhibit such clear behavior of local OCS sources during October. ΔOCS were -17, -16 and +25 ppt at 7:00 UTC and 0, -16 and +70 ppt at 9:30 UTC for upwind, target, and downwind locations, respectively. The air masses were predicted to be influenced by regional sources, as FLEXPART suggests low residential periods in the urban area. There was moderate vertical air mixing (PBLH from 200 m at 7:00 UTC to 500 m at 9:30 UTC) and weak atmospheric stability (Table 1).

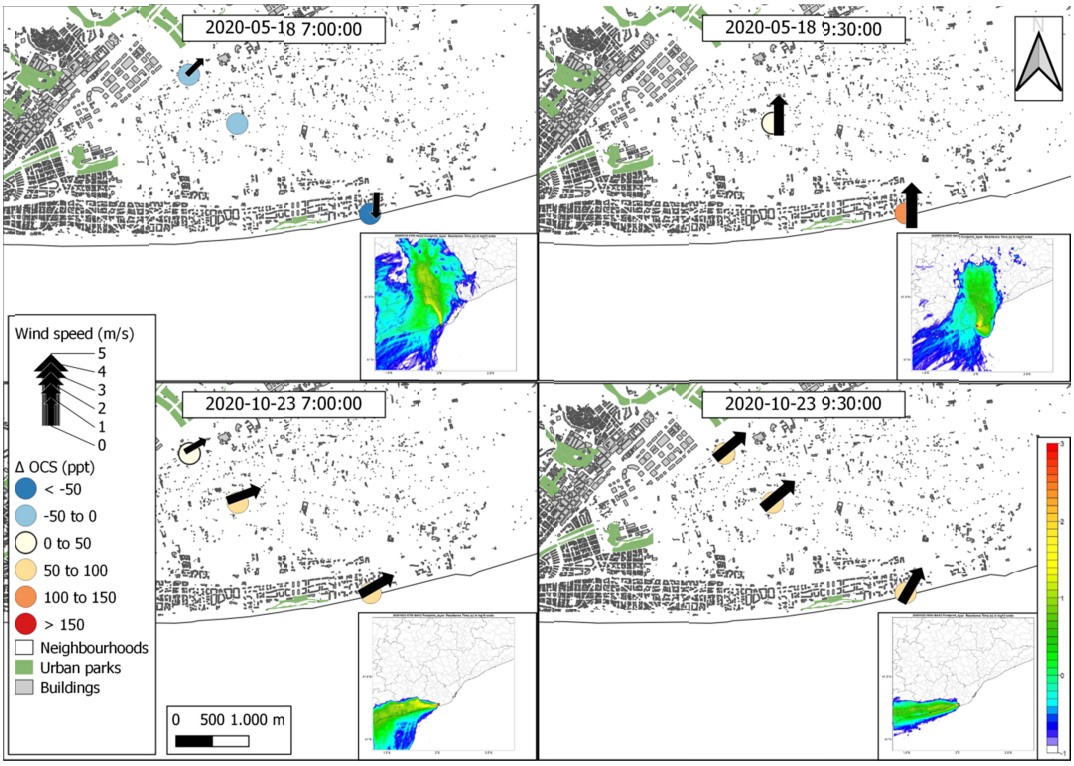
Agricultural: The Gavà and El Prat sampling sites are located in the Llobregat River basin, which is mostly dedicated to peri-urban agriculture. Of the 5,500 ha of urban agricultural land at the AMB, over 2,800 ha are in this basin, as shown in Fig. 1. The main agricultural products grown in this area are horticultural crops (such as lettuce, tomatoes, peppers, and artichokes), herbaceous crops, fruits, and some cereals (such as barley and alfalfa), and many short-cycle crops that are interannually rotated and well irrigated. Only the upwind site of Gavà is on the coast alongside the built infrastructure and urban forest and outside an agricultural field (sees supporting information Appendix S2 for pictures). The El Prat airport is nearby and between 3 and 5 km east to El Prat and Gavà, respectively. Gavà values were a clear example of how the wind component affected OCS mixing ratios since it is surrounded by the sea (south), agricultural and natural land (west to north) and is influenced by the port and the airport to the east.

Fig. 7a shows low OCS concentrations well below the background values with ΔOCS of -67, -+52, and -32 at 7:00 UTC in May during full photosynthetic activity of grown herbaceous fields,

644 which indicates the drawdown of OCS by vegetation. The wind measured on site was mostly
645 from the north, especially for the downwind site, as confirmed with the FLEXPART trajectory,
646 which predicts a high residential time for air masses coming from the north where the
647 agricultural fields are located. This indicates that the OCS drawdown might not be entirely a
648 local effect of agriculture but could also be due to a more regional effect of COS taken up by
649 soil and vegetation during the night all over Catalonia and then advected by the land breeze
650 over the AMB. However, by 9:30 UTC, OCS concentrations increased (up to an ΔOCS of +116
651 for the downwind site) when air masses were coming from the urban and port areas and
652 despite PBLH development, which reached 1380 m that morning. During the October
653 campaign, southwesterly winds predominated both at 7:00 and 9:30 UTC, which brought in air
654 masses from the port and Gavà urban area with high industrial activity resulting in ΔOCS
655 between +82 and +40 ppt at 7:00 UTC. At 9:30 UTC, ΔOCS values decreased slightly and had
656 less variability ranging from +49 to +55 ppt, and this indicated a more homogenous air mixture
657 due to a more developed PBL, which increased from 21-84 to 380-519 m for that location.
658 During October, air transport had much more influence on the OCS budget than the
659 agricultural land use as it did during the May campaign when the fields were in full
660 photosynthetic activity.
661 The opposite behavior was observed at the El Prat agricultural site, where a deep PBLH (1200
662 m) and regional air mass influence occurred in May, while a more stable situation and lower
663 PBLH (691 m) dominated in October. In general, the values were similar to the background OCS
664 for May with ΔOCS values of +25, +37, and +22 ppt at 7:00 UTC and even higher enhancements
665 at 9:30 (+17, +44 and +173 ppt, Fig. 7b). FLEXPART back trajectories in May showed air masses
666 coming from the east with longer residential times located in the sea but still received
667 influence from the airport and the port of Barcelona. During the October campaign, El Prat had
668 higher OCS enhancements at both sampling times (ΔOCS of +70, +33 and +80 ppt for 7:00 UTC;
669 +7, +122 and +77 ppt for 9:30 UTC), which, given the low PBLH, suggests a local OCS source.

675 The FLEXPART showed that air masses came from the east indicating marine influence and/or
676 from the port of Barcelona, where activities, such as air navigation and maritime traffic, had
677 recovered 100% after the lockdown. The lower OCS concentrations in May compared to
678 October highlight the significant sink of agriculture during the growing season as was seen for
679 the Gavà location.

676 A) Gavà



677

678 B) El Prat

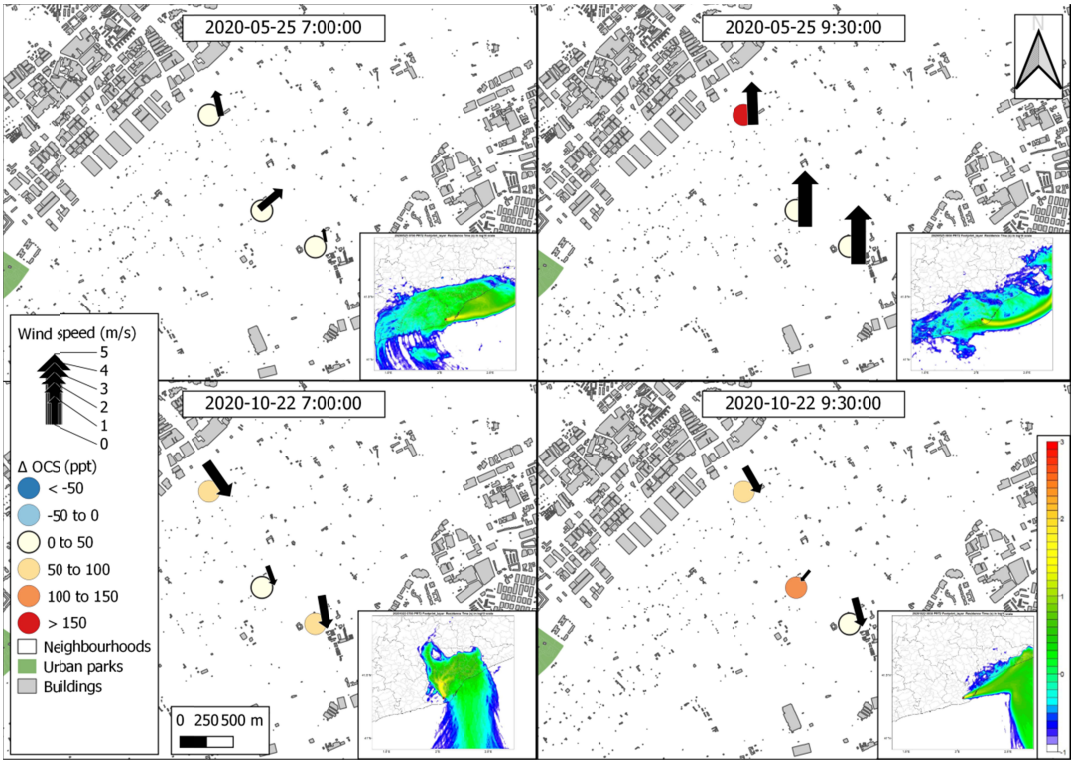


Fig. 7. OCS enhancement (Δ OCS) in ppt calculated as the measure of OCS minus background OCS (484 ppt for May and 407 ppt for October) for each campaign at the two urban parks as follows: a) Gavà and b) El Prat. The black arrow shows the wind direction and speed measured on site, and the absence of an arrow indicates that there was no wind blowing at the moment of measurement. A small map embedded in the lower right-hand corner of each panel shows the residence time on a logarithmic scale of the air masses arriving at the sampling site as determined with the FLEXPART model.

4.2. Considerations for OCS studies in urban ecosystems

Anthropogenic emissions are the primary source of OCS on a planetary scale, followed by oceanic flux (Remaud et al., 2023), they are significant at the local and urban scales. In our study, the peaks of OCS concentrations were mostly due to air masses coming from the port or the city, as was the case for Montjuic in October or Gavà during the May campaign, and reached values of 665 ppt for Montjuic and 600 ppt for Gavà (up to ΔOCS of +258 and +193 ppt, respectively).

There are various potential sources of OCS in urban areas, such as the erosion of automobile tires against asphalt, vehicle exhaust fumes, natural gas combustion and industrial processes including oil refineries and aluminum production (Yan et al., 2019). In fact, in their inventory,

696 Yan et al. quantified the total emissions in 2015 for China alone as 174 Gg S yr^{-1} with the
697 highest contributions coming from industrial OCS emission processes (120 Gg S yr^{-1}). In that
698 same study, the total vehicle exhaust was responsible for 3 Gg S yr^{-1}, which is approximately
699 half of the yearly global estimate of 6 Gg S yr-1 given by Lee and Brimblecombe (2016). The
700 latter study also indicated that the heavy fuel oil used in ships is a significant source of the OCS
701 budget and produces 30 Gg S yr^{-1}. The AMB qualifies for all these potential sources and it has a
702 heavily transited marine port that also has a combined cycle gas turbine power plant that runs
703 on natural gas as well as an intense use of private vehicles within the city.

704 Additionally, a broad variety of sulfides are produced by wastewater where volatile organic
705 compounds (VOC) such as MeSH, DMS, CS2, DMDS, DMTS and OCS are generated in anoxic
706 environments of sewers (Lee and Brimblecombe, 2016), and it has been noted that the
707 microbial activity in these anoxic sediments is closely linked to the production of OCS (Kitz et
708 al., 2019). Sulfide emissions from urban wastewater networks are frequently detected due to
709 their bad odor as is the case for Barcelona (Eijo-Río et al., 2015) and Thessaloniki (Besis et al.,
710 2021). In our study, the sampling sites of Sagrada Familia in October (ΔOCS of +150 ppt) and
711 Poble Nou (ΔOCS of +50 ppt) concur with locations of a combined sewer system previously
712 reported to have high peaks of H_2S, which indicated a potential OCS source from wastewater.
713 Unfortunately, constraining this signal from other potential urban sources was out of the
714 scope of this study.

715 In terms of vegetated land uses, we found one case of a significant OCS drawdown in
716 agricultural sites during the growing season of May. In addition to photosynthetic uptake
717 (Campbell et al., 2017, 2008; Montzka et al., 2007), waterlogged soils have been reported to
718 act as sinks of OCS when planted with crops (Yi et al., 2008). The agricultural fields of the
719 Llobregat basin are mostly irrigated by inundation, which could further intensify the OCS
720 uptake and explain the OCS drawdown at 7:00 UTC when photosynthetic activity was high. We

721 also found values indicating uptake during the growing season in Collserola Forest, which is in
722 agreement with other studies evaluating forest OCS uptake (Belviso et al., 2016; Campbell et
723 al., 2017, 2008).

724 Finally, determining the influence of land use on the overall urban OCS budget requires a
725 reliable background measurement. In general, background levels for OCS are associated with
726 air masses coming from the sea because the stability provided by oceans results in constant
727 OCS concentrations, at least at a seasonal scale (Montzka et al., 2007), as was the case for San
728 Francisco (Villalba et al., 2021). However, this is not applicable for the AMB because the
729 convection regime is quite peculiar. The AMB has a unique land–sea air mass exchange in
730 which sea breezes under specific conditions do not bring new air masses but rather recycle air
731 masses that originated over the urban area, however, a deeper research should be done in this
732 regard, since marine contribution cannot be neglected. This type of process has been observed
733 by Jaén et al. (2021), who described how ozone plumes stay over the shore due to advective
734 processes during heat episodes such as heatwaves. The thermal component of convective
735 processes creating episodes of air recirculation on the Spanish eastern coast has also been
736 documented by Millán et al. (2000), where they outline how the sea breeze can favor the
737 formation of layers of stratified air reservoirs in heights where compounds accumulate that
738 can later return to the land. This particular sea breeze circulation constricts local ventilation
739 and exacerbates the accumulation of anthropogenic gases emitted in the AMB.

740

741 **5. Conclusions**

742 We performed two measurement campaigns of OCS mixing ratios in the Metropolitan Area of
743 Barcelona (AMB) to explore to what extent different urban land uses can have an impact on
744 the OCS mixing ratios measured on flask samples regarding a particular urban climate,
745 geography, and topography of AMB. Air samples were taken at locations representing four

746 different land uses as follows: urban parks, forests, agricultural fields and impervious urban
747 landscapes.

748 Based on the interflask comparison described in 2.3, we determined that the OCS
749 measurement uncertainty can be as high as +53 ppt, which reflects that near-surface
750 measurements in urban heterogeneous environments result in higher uncertainties than in
751 homogenous rural environments. We also compared average OCS concentrations ±σ with
752 values observed from ICOS- LSCE in Gif-sur-Yvete (GIF), which were taken at the same moment
753 as our campaign (Fig. S3). We observed how mean OCS concentrations and σ in the AMB were
754 systematically higher than in GIF, which suggests that anthropogenic emissions could affect
755 the increase in uncertainty.

756 The ability to capture a photosynthetic signal appears weak in vegetated areas within the city,
757 such as parks, and is relegated to forests and peri-urban agricultural areas. Urban parks
758 showed values significantly higher than the established background value, both in May (i.e., up
759 to +144 ppt) and in October (i.e., up to +150 ppt), which shows the influence of anthropogenic
760 sources, possibly from the port and the city center, which masks the possibility of capturing
761 the signal from the vegetation. The urban forest suggested OCS uptake values up to -33 ppt,
762 which indicates a significant photosynthesis sink in denser vegetation masses even within city
763 limits.

764 The urban area showed a variety of signals from almost neutral to above the background
765 value, which suggests nearby emission sources. In our case, we found the explanation of some
766 process values that may be aligned with urban traffic but above all with the industrial activity
767 of the port and airport (for example, high OCS values in Montjuic when the wind came directly
768 from the port). We can also think of other biogenic processes that produce OCS processes
769 linked to human activity on urban land such as the waste system. These processes should be
770 studied in more detail in future works. We have not been able to capture an effect of urban

771 vegetation on OCS uptake; instead, the peri-urban area of agriculture and forests may have
772 more important roles in the OCS dynamics in cities.

773 Last, agricultural areas showed a clear drawdown during the growing season for the location of
774 Gavà, where we were able to discard regional influences and intense air mixing. OCS
775 enhancements in October reflect the loss of photosynthetic uptake and the return to business
776 as usual traffic and nearby airport and port activities.

777 Overall, the variability of OCS in the urban ecosystem was higher than we expected. The
778 URBAG campaigns of OCS measurements showed evidence that the use of OCS as a trace gas
779 to determine the contribution of the urban biosphere to the CO_2 budget is a complicated task
780 and that the vegetation signal is difficult to detect because local anthropogenic activities have
781 a significant influence. The urban ecosystem is complex in terms of land uptake, marine
782 emissions, and anthropogenic emissions from the city port, and strongly impacts the spatial-
783 temporal distribution of OCS in the AMB and impedes a clear constraint of the biosphere
784 signal.

785 **Acknowledgments**

786 This work has been made possible thanks to the financial support of the European Research
787 Council (ERC) Consolidator project: Integrated System Analysis of Urban Vegetation and
788 Agriculture (818002-URBAG), the Spanish Ministry of Science, Innovation and Universities,
